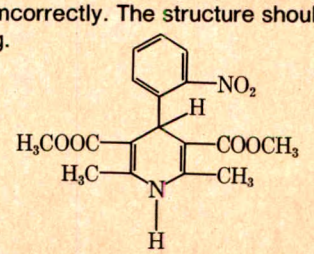
CORRECTION

In the February 18, 1982 issue on page 500 (*Millard RW et al: Differential Cardiovascular Effects of Calcium Channel Blocking Agents: Potential Mechanisms*), the structural formula for nifedipine in Figure 1 presents the ring bonds incorrectly. The structure should show 3 double bonds in the upper ring and 2 in the lower ring.

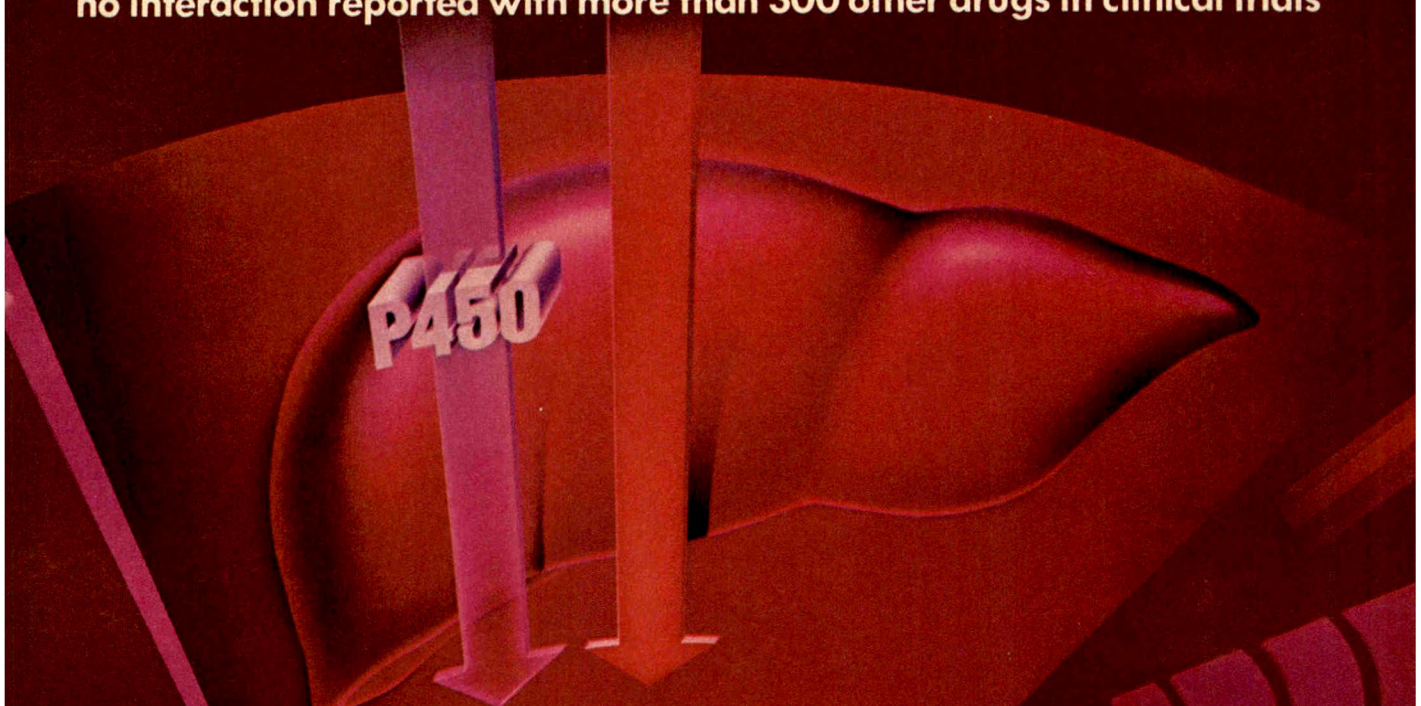


Action without interaction

when given with drugs that utilize the P450 system*

- unlike diazepam and chlordiazepoxide, no interaction with cimetidine
- unlike diazepam, clearance not delayed by oral contraceptives

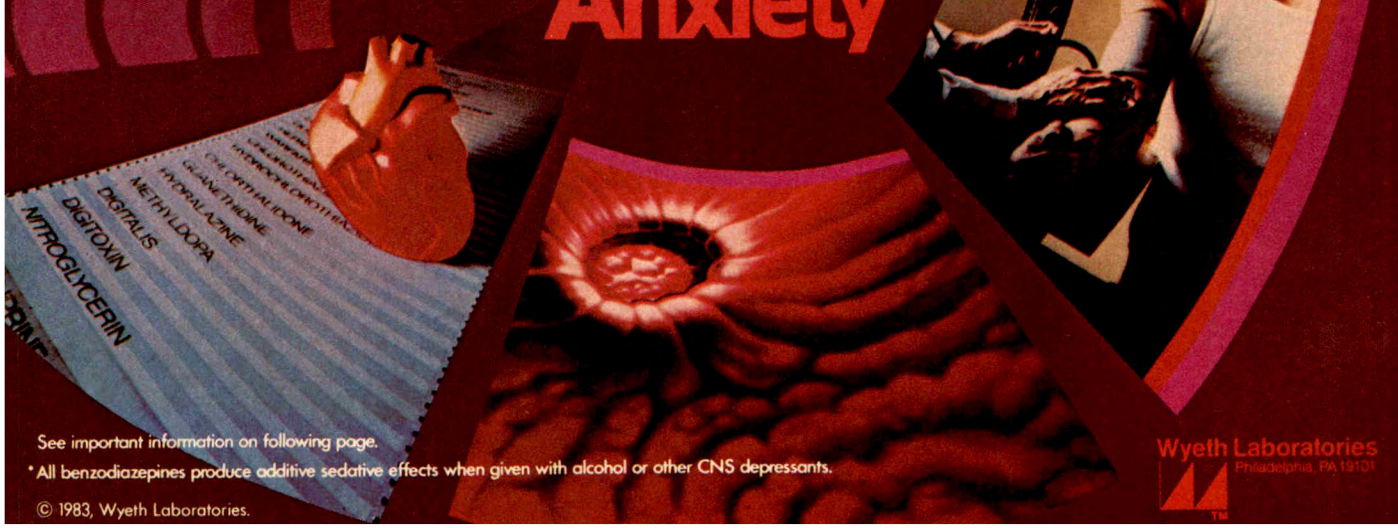
no interaction reported with more than 300 other drugs in clinical trials*



Agent of change

Ativan® (lorazepam)(IV)

for Anxiety



See important information on following page.

*All benzodiazepines produce additive sedative effects when given with alcohol or other CNS depressants.

NEW TABLET DESIGN 0.5, 1.0 and 2.0 mg

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® (lorazepam) for Anxiety

DOSAGE: Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.

HOW SUPPLIED: 0.5, 1.0 and 2.0mg tablets.

Wyeth Laboratories

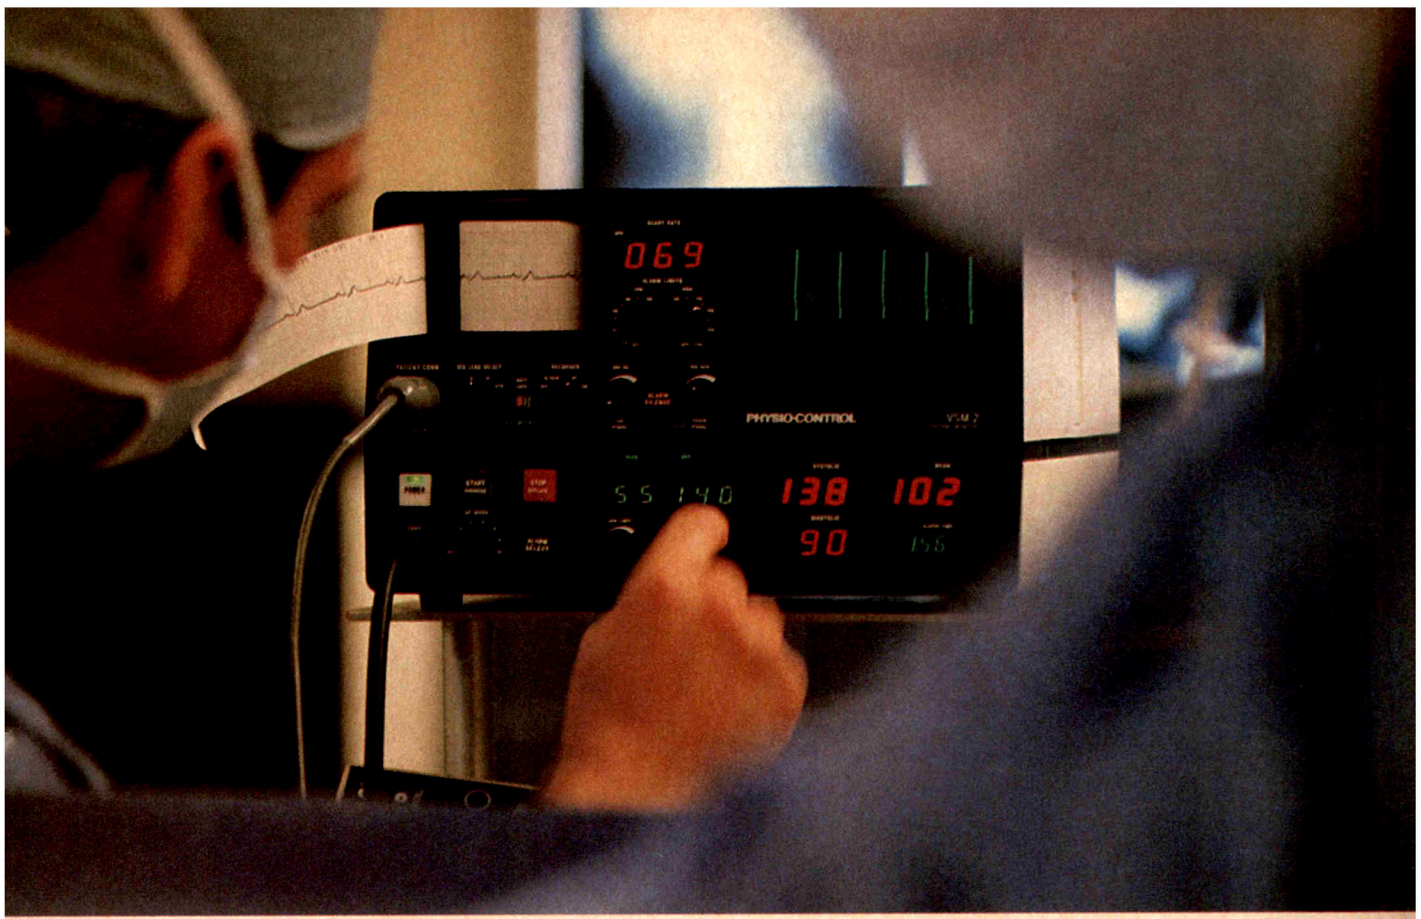
CLASSIFIED

BEYOND THE BEAUTIFUL BEACHES OF TIDEWATER. . .

. . .lies a largely affluent patient population of 825,000, and with it, an excellent opportunity for a Cardiologist well-versed in nuclear technology. The private practice we're referring to is affiliated with one of the Tidewater area's most distinguished hospitals, a 200+-bed acute care facility featuring state-of-the-art equipment throughout, full ancillary services, a new professional building next door, and a location that is a short ride away from the Atlantic Ocean.
This physician can count on a solid referral base and good cross coverage in addition to all the lifestyle advantages of living in one of the top vacation spots in the southeastern U.S. Earning potential is superb. For further information, call or send your curriculum vitae to: Pam Catlett, Professional Relations, Post Office Box 1438, Louisville, Kentucky 40201. Toll-Free: 800/626-1590.

CARDIOLOGIST WANTED, Board Certified or Board Eligible, with training in invasive and noninvasive procedures. M.D. degree must be from a U.S. medical school. Attractive salary with potential partnership in two yrs. Great Lakes Area. Please send curriculum vitae and references to: Box 290, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CARDIOLOGIST, ACADEMIC—Three tenured tract positions available now at Asst or Assoc Professor level. WANTED—Persons with experience in Clinical Research in ECHOCARDIOGRAPHY and/or INVASIVE ELECTROPHYSIOLOGY and/or BASIC RESEARCH IN THE CIRCULATION. Send resume and names of three references to Robert Zelis, MD, Cardiology, Penn State Univ, Hershey Medical Center, Box #850, Hershey, PA 17033 by Nov. 1, 1983 or call (717) 534-8407. An Affirmative Action/Equal Opportunity Employer.



More monitoring. Less space.

One VSM®2 noninvasive vital signs monitor gives you the kind of patient monitoring you'd expect from a combination of three or four instruments.

It gives you ECG, heart rate, temperature, blood pressure, time, date. All documented. All in one. All visible at a glance.

And it gives you this vital information anywhere in the hospital because it's battery operated, compact, portable.

Use it alone. Or with our LIFEPAK®6s defibrillator/monitor or CMS™ 6000 central monitor.

Either way you'll find it answers your needs with total monitoring capability, dependable performance, and outstanding support worldwide.

Manufacturers of the LIFEPAK family of defibrillator/monitors.

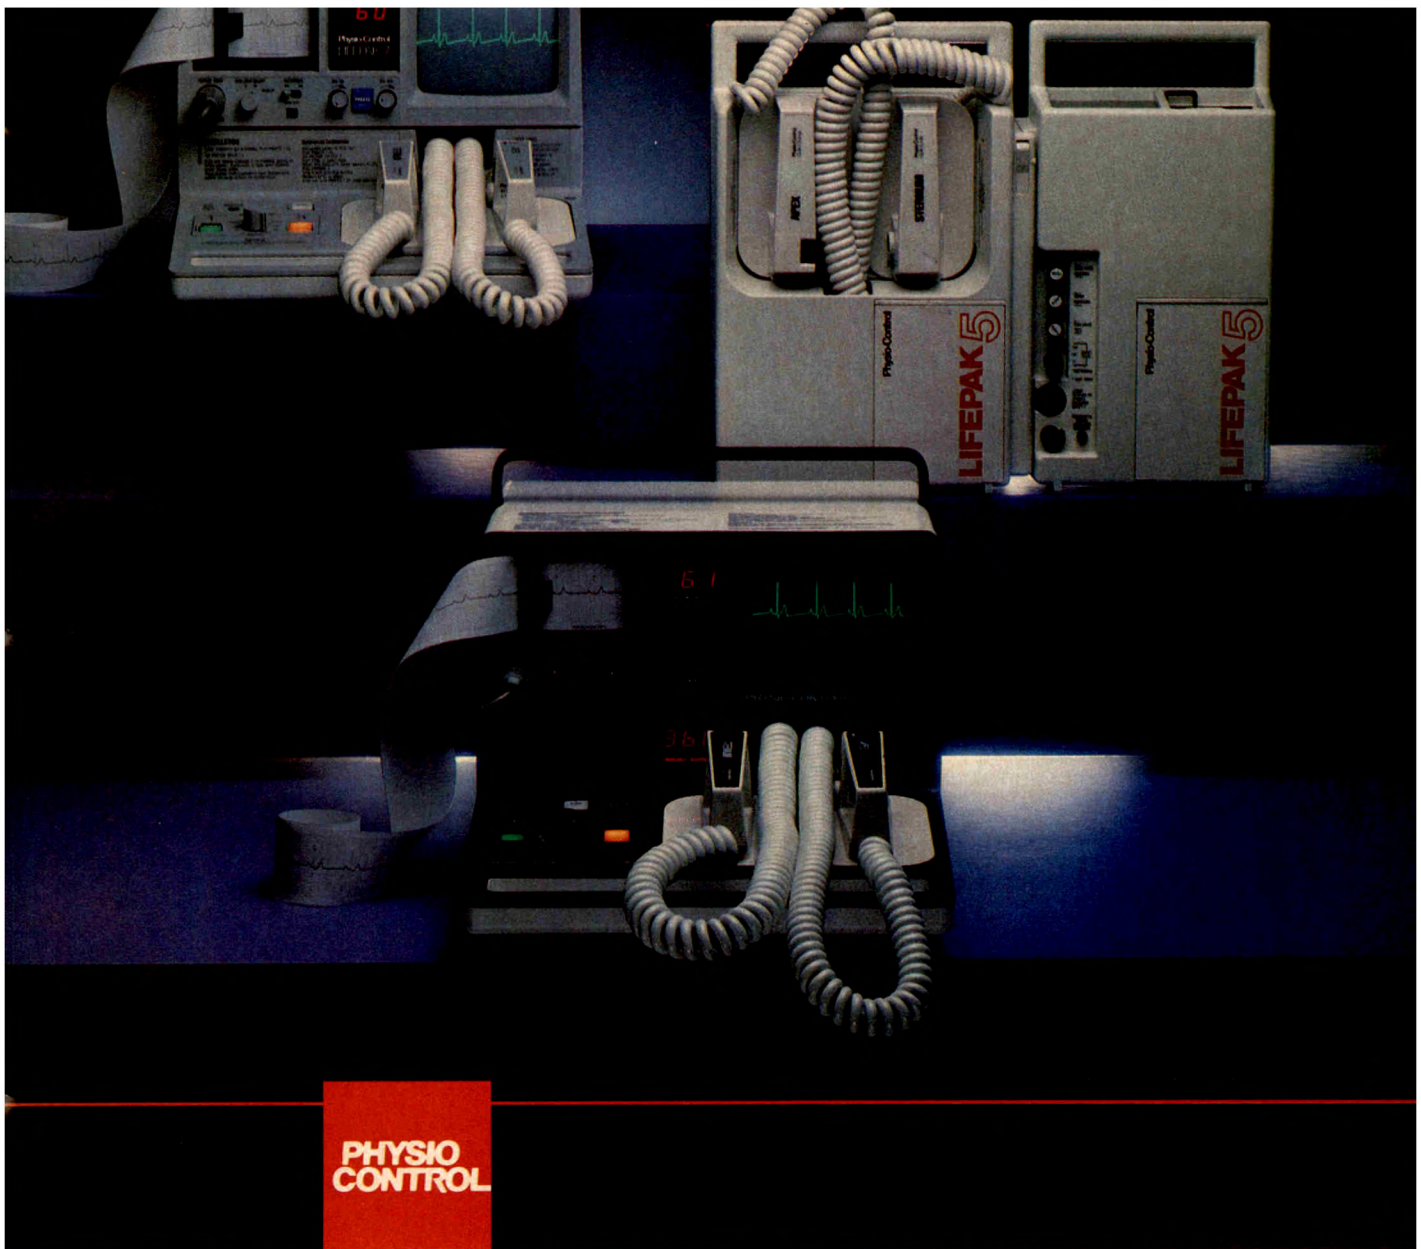
Animal Behavior—Human Behavior—Cardiac Behavior

Considerable study has been made through the years of behavioral characteristics of nonhuman animals—how they communicate, court, mate, fight, care for their young, acquire food, care for their bodies, and so on. Similar studies of humans, of course, are being performed constantly. In contrast to studying general features of one species or another, the pages of this journal focus on how the heart behaves under natural and unnatural conditions, primarily in humans, but in 10% or so of its pages, in nonhuman animals. Our methods of studying the heart change with the changing of our "instruments of precision," our pharmacopia and our ideas, but all the while the heart remains more or less unchanged. Despite the enormous amount of information gained about the heart in the last 75 years, in some respects we have not begun. Our knowledge of the *causes* of cardiac diseases remains poor. Our diagnostic and therapeutic abilities far exceed our knowledge of why the diseases occur in the first place. Despite not knowing precisely why most heart diseases occur, we do know how to prevent many of them. If our total serum cholesterol remains <150 mg/dl, our chances of developing atherosclerosis severe enough to obstruct or aneurysmally dilate an artery are extremely small. If we totally discard salt from the diet, our chances of developing systemic hypertension and all of its consequences, including stroke, are virtually nonexistent. If we live in sanitary, uncrowded and nonpromiscuous environments, our chances of developing rheumatic and syphilitic heart disease are minimal. If alcohol intake is not abused, our chances of developing our most common primary myocardial disease—dilated cardiomyopathy—are relatively small. Thus, most of our present-day common cardiologic conditions are acquired, man-made, of our own doing. The congenital cardiac conditions—holes in cardiac septa, obstructions to flow into or out of a cardiac chamber, improperly connected arteries and veins, malformed valves (bicuspid), which are prone to degenerate (calcific) or to become infected, floppy mitral valves and hypertrophic cardiomyopathy—will remain despite our alterations in dietary and living habits. As we continue to learn more about, and do more for, heart disease, it is humbling to reflect that the heart is only one of the bodies' many organs and that our major subjects of study are only one of the many species on this earth.

William C. Roberts, MD
Editor-in-Chief



PHYSIO CONTROL

The First Family

Saving lives isn't always easy.

For over 20 years the PHYSIO-CONTROL® LIFEPAK® family of defibrillator/monitors has helped — with advanced, easy-to-use features. And dependable, time-tested equipment. Products that the competition uses as a standard for measuring their own performance.

We were first to give you a complete family of defibrillator/monitors. First to give you 1-2-3 ease of operation.

And we're still first to listen to your needs. With products that answer the problems of today and lead the way with solutions for tomorrow.

(ateno

Tab

*Cardioselectivity denotes a relative preference for β_1 receptors, located chiefly in cardiac tissue. This preference is not absolute.

See last page of this advertisement for brief summary of prescribing information.

ST

TENORMIN® (atenolol)

A beta$_1$-selective blocking agent for hypertension.

INDICATIONS AND USAGE: TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a beta$_2$-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

U.S. STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS U.S. AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

Miscellaneous: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

Bradycardia: Atropine or another anticholinergic drug.

Heart Block (Second or Third Degree): Isoproterenol or transvenous cardiac pacemaker.

Congestive Heart Failure: Conventional therapy.

Hypotension (Depending on Associated Factors): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

Bronchospasm: Aminophylline, isoproterenol, or atropine.

Hypoglycemia: Intravenous glucose.

DOSAGE AND ADMINISTRATION: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m^2 (normal range is 100-150 ml/min/1.73 m^2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (ml/min/1.73 m^2)	Atenolol Elimination Half-life (hrs)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

HOW SUPPLIED: Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

CORONARY HEART DISEASE

431 Effect of Interventions in Salvaging Left Ventricular Function in Acute Myocardial Infarction: A Study of Intracoronary Streptokinase

FLORENCE H. SHEEHAN, DETLEF G. MATHEY, JOACHIM SCHOFER, HANS-JOACHIM KREBBER, and HAROLD T. DODGE

The effect of intracoronary streptokinase on left ventricular (LV) function in acute myocardial infarction (MI) was studied from serial contrast angiograms in 52 patients. Hypokinesia in the MI region improved in 17 of 42 reperfused patients (40%) and in 0 of 10 nonreperfused patients. The ejection fraction did not change in reperfused patients because ejection fraction was normal acutely due to hyperkinesia on the opposite wall and hyperkinesia decreased subsequently, masking the improvement in hypokinesia. Regional LV wall motion must be measured to assess the effect of therapeutic interventions. Early thrombolysis in acute infarction improves LV function.

439 Hemodynamic Effects of Intravenous Prostacyclin in Stable Angina Pectoris

BRIAN G. FIRTH, MICHAEL D. WINNIFORD, WILLIAM B. CAMPBELL, and L. DAVID HILLIS

Prostacyclin (PGI_2) is a naturally occurring vasodilator and inhibitor of platelet aggregation. In this study, the safety and efficacy of incremental doses of intravenously infused PGI_2 were evaluated in patients with coronary artery disease and stable angina pectoris. Ten patients received PGI_2 (maximum dose 10 ng/kg/min) and 7 received placebo. In this dosage, PGI_2 produced flushing but no other adverse effects. It caused an increase in heart rate and cardiac index and a decrease in systemic and pulmonary vascular resistance, without a significant decrease in pulmonary arterial or capillary wedge pressure. There was a concomitant reduction in coronary vascular resistance, which was generally accompanied by an increase in both arterial and venous 6-keto $PGF_{1\alpha}$ concentrations, but no demonstrable change in plasma renin activity.

444 An Improving Prognosis Over Time in Medically Treated Patients With Coronary Artery Disease

DAVID B. PRYOR, FRANK E. HARREL, Jr., KERRY L. LEE, ROBERT M. CALIFF, and ROBERT A. ROSATI

The national mortality rate from coronary heart disease has decreased during the past decade, but the reasons for this decrease are not clear. A decrease in both the mortality rate and total cardiovascular events occurred during the last 10 years in 1,911 medically treated patients with significant coronary artery disease. This decrease cannot be explained by less sick patients being referred for evaluation. This study suggests that at least part of the decrease in coronary heart disease mortality observed nationally is occurring in patients with established coronary disease.

449 Directional ST-Segment Deviation in Graded Exercise Tests Correlated With Motion of the Individual Segments of the Left Ventricular Wall

JAMES N. KARNEGIS, JOHN MATTS, NAIP TUNA, KURT AMPLATZ, RICHARD B. MOORE, HENRY BUCHWALD, and the POSCH Group

The relation of the direction of exercise-induced ST-segment deviation to the specific patterns of motion of the individual segments of the left ventricular (LV) wall was investigated. The first 280 subjects to enter the Program of Surgical Control of Hyperlipidemia (POSCH) were studied by treadmill exercise testing and left ventriculography. All subjects had had 1 previous myocardial infarction and had hyperlipidemia. The results showed that (1) ST-segment elevation with exercise in these subjects is infrequent, (2) exercise-induced ST-segment elevation

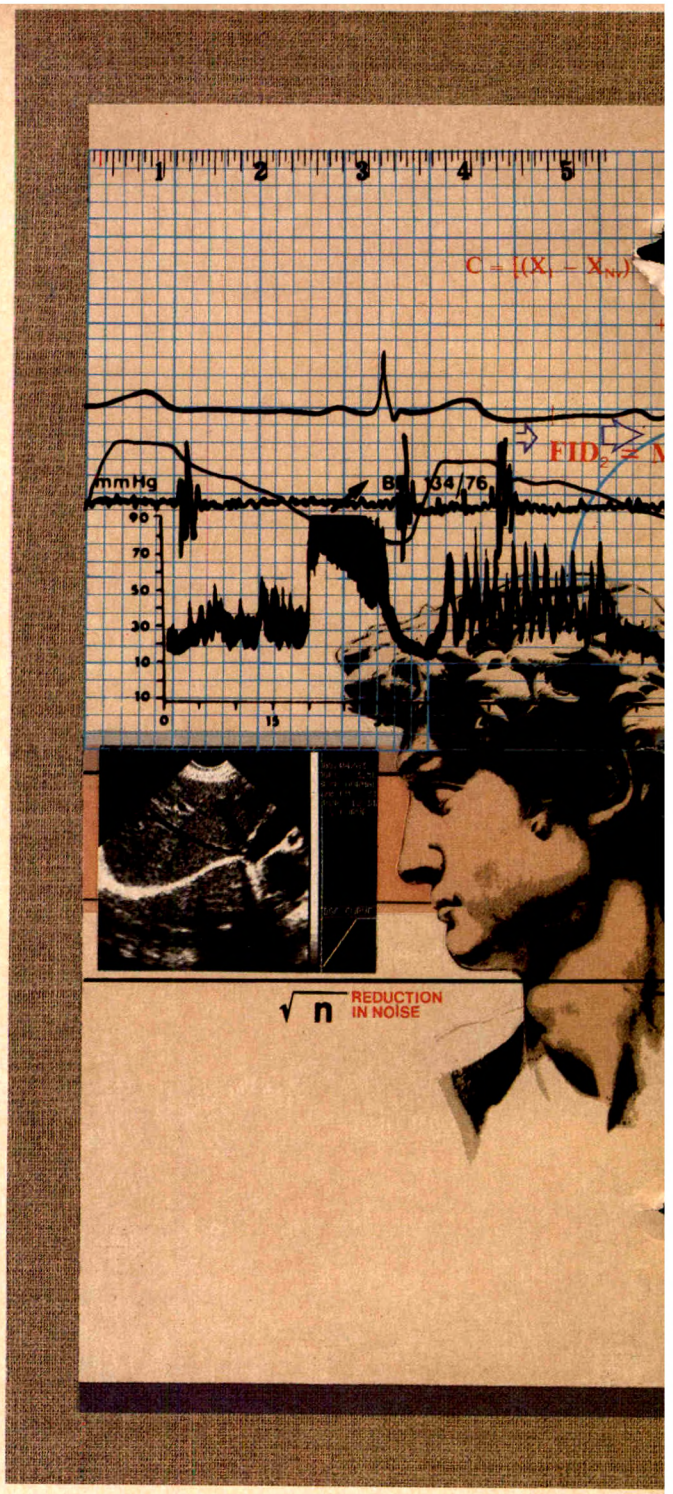
The New Tradition is technological excellence.

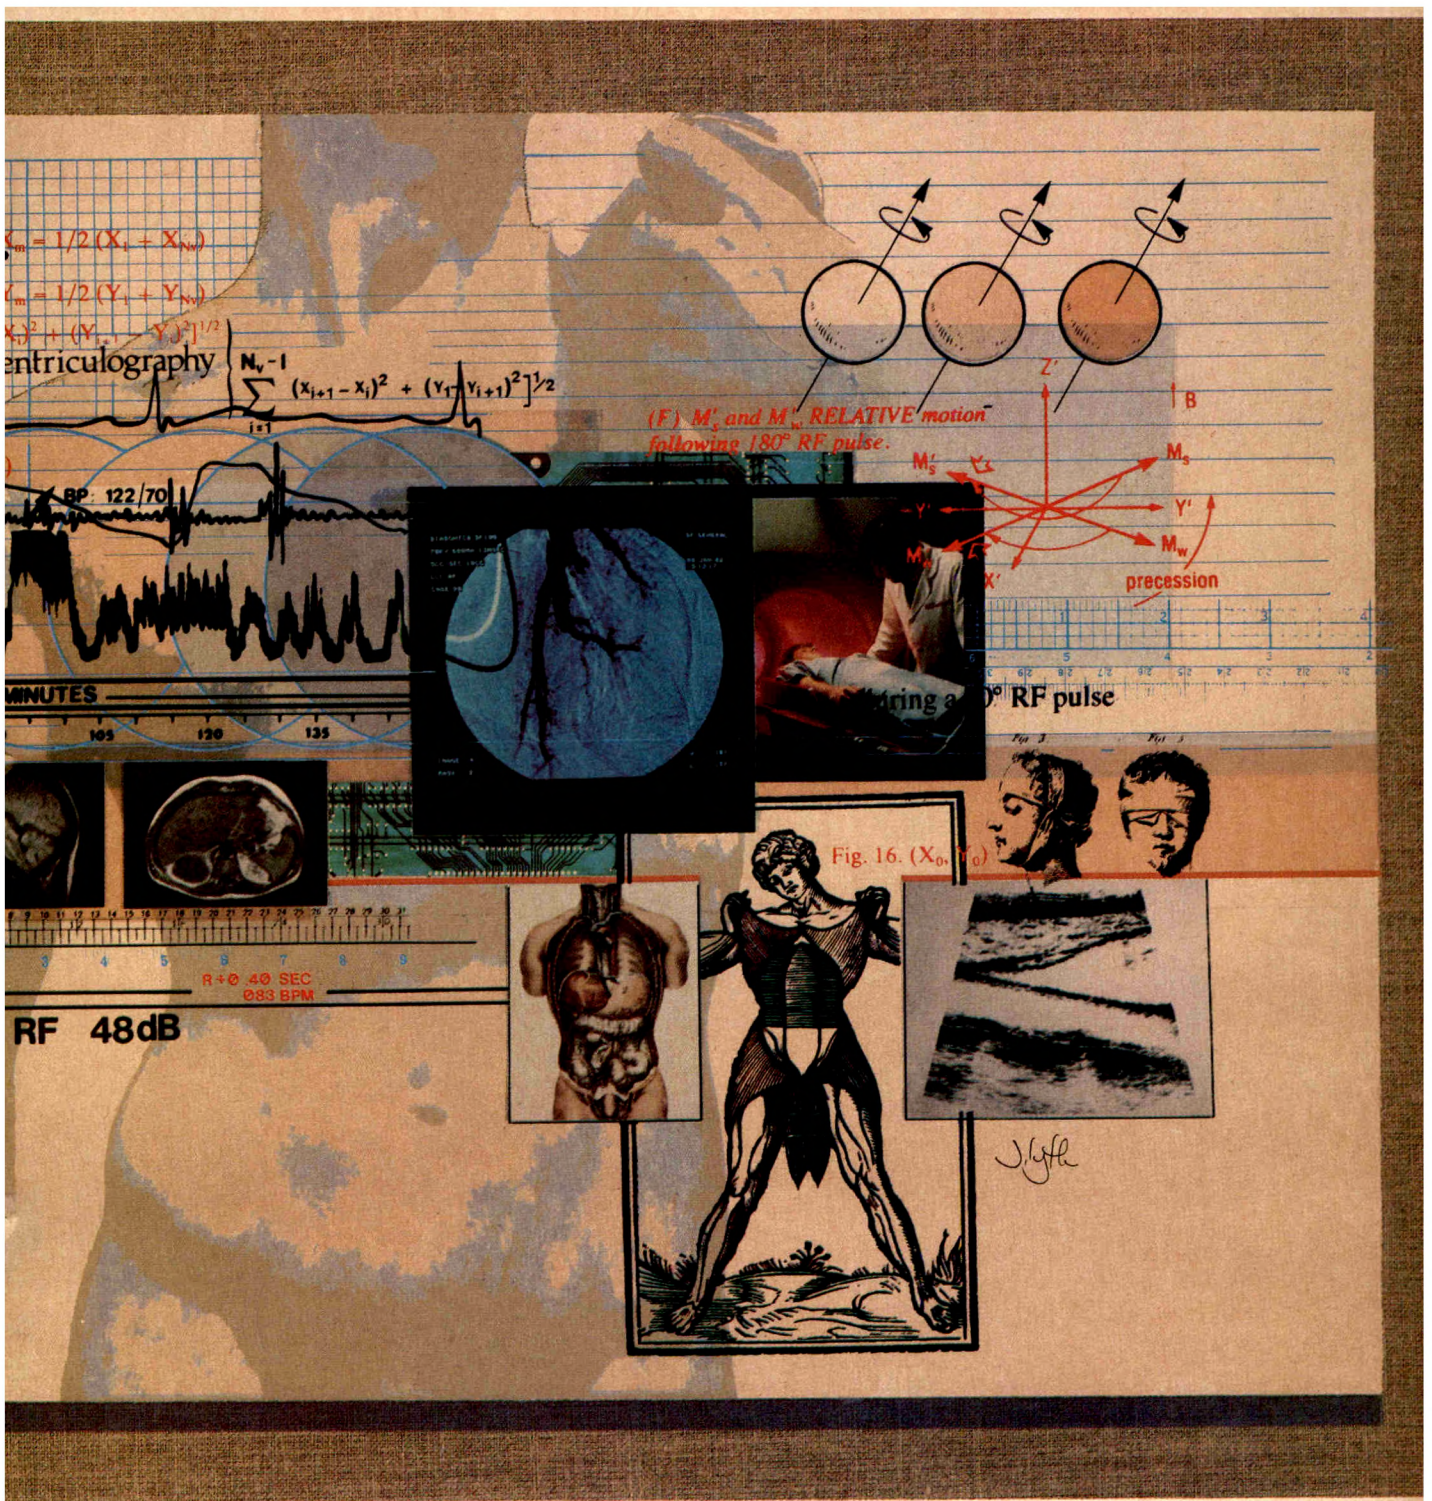


Technology is changing the way medical professionals view companies who manufacture medical systems.

In the same way it has changed methods used to perform clinical procedures, technology has ushered in a new tradition of technically advanced companies.

Leading this new tradition of technological excellence is Diasonics. No other company in the field of diagnostic imaging has consistently proven itself and its systems to be the standard by which others follow.

Diasonics Ultrasound, Digital X-ray and NMR imaging systems bring each user to the current limits of imaging quality and clinical versatility.



Technology and Medicine interpreted by John A. Lytle

And while Diasonics is a company driven by technological leadership and innovation it is also a company where traditional service, education and customer support are cornerstones.

Clinical value is the basis by which Diasonics moves from one technical advance to the next. It is a basis you might consider when moving from the old to the new tradition.

DIASONICS

Indications: Premature atrial and ventricular contractions, aproxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, paroxysmal ventricular tachycardia when not associated with complete heartblock, maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

Contraindications: Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Warning: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting in extremely rapid ventricular rate.

Precautions: All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, light-headedness, and tremor; (3) G.I. symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at the rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.

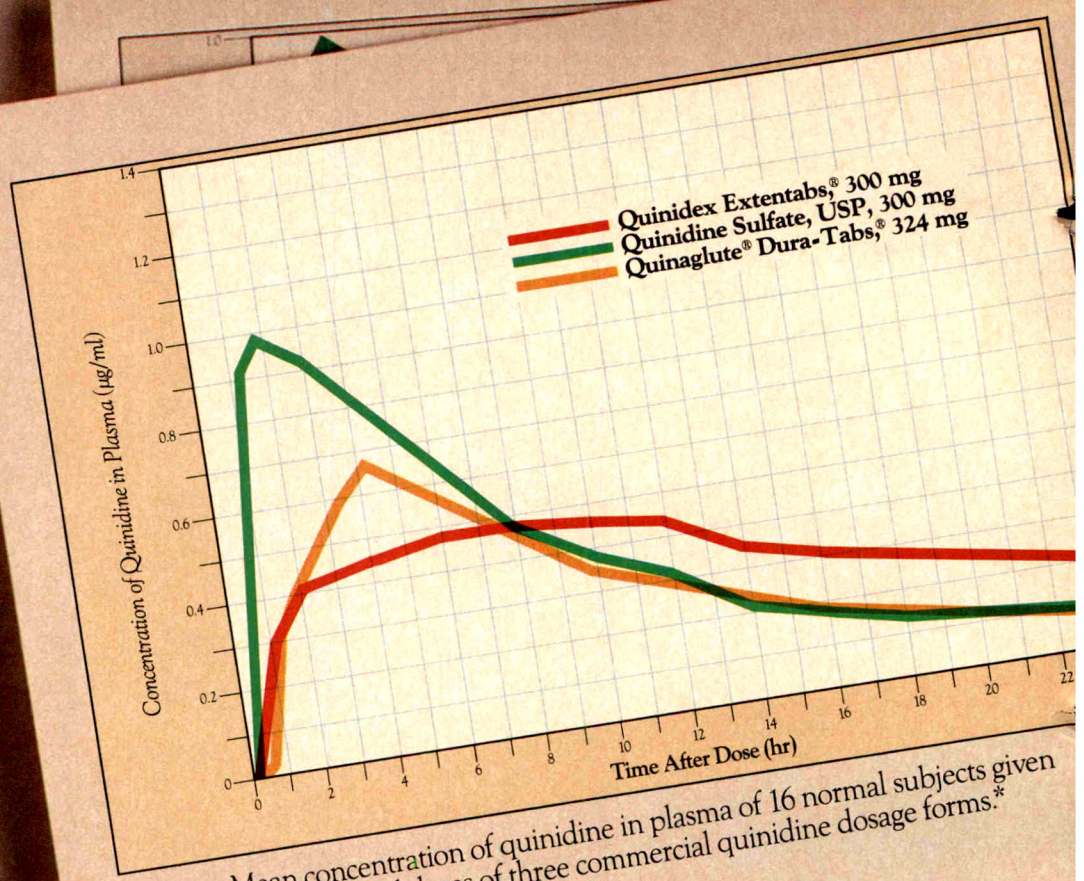
NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G.I. symptoms can also be minimized by giving the drug with food.

Adverse Reactions: Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

Dosage: Two Quinidex Extentabs every 8 to 12 hours.

How Supplied: White sugar-coated Extentabs in bottles of 100 (NDC 0031-6649-63) and 250 (NDC 0031-6649-67) and Dis-co® Unit Dose Packs of 100 (NDC 0031-6649-64).

Rev: Dec. 1981



Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

Consider The Evidence For Quinidex (Quinidine Sulfate, USP), 300 mg Extentabs®

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product

*Some patients may require a t.i.d. dosage schedule.

For the proof, ask your Robins representative for a copy of the controlled crossover study. Or write S. Tisdale, M.D., 1211 Sherwood Avenue, Richmond, Va. 23220.

can occur without evidence in the resting subject of either LV aneurysm or dyskinesia, (3) the group of subjects who had ST-segment elevation with exercise compared with the group in whom ST-segment depression developed had a much greater area of damage to the LV wall, and (4) LV segmental wall motion abnormalities clustered in the inferoposterior area in the group with exercise-induced ST-segment elevation but tended to be scattered throughout the various segments of the LV wall in the group with exercise-induced ST-segment depression.

453 Hemodynamic Effects of Felodipine at Rest and During Exercise in Exertional Angina Pectoris

JEAN-MARIE DETRY, PATRICK M. De COSTER, and JEAN RENKIN

Felodipine, a new calcium antagonist, had a clear antianginal effect in 8 patients whose exercise capacity increased by 20% after oral intake of the drug. The major hemodynamic change observed after felodipine was a decrease in the systemic vascular resistance at rest and during submaximal and maximal exercise. The prevention of angina pectoris was accompanied by significant hemodynamic and electrocardiographic improvements, although the pressure-rate product was unmodified; after felodipine, the maximal pressure-rate product was higher but the electrocardiographic abnormalities were unchanged. These changes in the anginal threshold and in the relation between ST-segment depression and pressure-rate product suggest an improved oxygen delivery to the myocardium.

458 Morphology of Ventricular Premature Beats as an Aid in the Electrocardiographic Diagnosis of Myocardial Infarction

HAROLD DASH and THOMAS J. CIOTOLA

This study of the morphology of ventricular premature beats (VPBs) in the electrocardiographic diagnosis of myocardial infarction (MI) demonstrates that VPBs with a qR pattern are highly specific for MI. Of 760 consecutive patients who underwent cardiac catheterization, 58 had VPBs on the precatheterization electrocardiogram or rhythm strip. Twenty-one of these 58 had MI documented by left ventriculography. The morphology of VPBs had low sensitivity (29%) but high specificity (97%) and predictive value (86%) for the diagnosis of prior MI. VPB analysis complemented the standard electrocardiographic diagnosis of MI in that 2 patients had their MI apparent only on VPB analysis.

462 Prognosis After an Initial Non–Q-Wave Myocardial Infarction Related to Coronary Arterial Anatomy

MICHAEL R. NICHOLSON, GARY S. ROUBIN, LOUIS BERNSTEIN, PHILLIP J. HARRIS, and DAVID T. KELLY

Eighty-six consecutive hospital survivors (aged ≤60 years) of a first non–Q-wave acute myocardial infarction (MI) were followed up prospectively. Coronary arteriography was performed a median of 2 weeks after MI. The size of the MI was small. Forty-nine patients had 1 vessel significantly narrowed by disease (≥70% luminal diameter reduction), and 19 had 2-vessel, 2 had 3-vessel, 3 had left main (≥150% luminal diameter reduction) and 13 had minimal or no coronary artery disease (CAD). Complete occlusion of the MI-related vessel was present in 33 patients. All 33 and an additional 5 patients had collateral vessels to the MI area. During a mean follow-up of 25 months, 1 cardiac death and 4 recurrent infarcts (3 with non–Q-wave MI) occurred. Angina occurred in 53 patients (62%) and responded medically in all but 7, who underwent coronary artery surgery. Angina after MI occurred frequently in patients with severe proximal left anterior descending CAD (≥90%), and in those with CAD (≥50%) in a vessel supplying collaterals to the infarct area. It is concluded that because angina can be managed medically in most patients and the outcome is good, routine coronary angiography is not indicated in asymptomatic survivors (≤60 years) of a first non–Q-wave MI.

466 Effects Induced on Blood Platelets in Ischemic and Nonischemic Myocardium

ERIK THAULOW

Platelet aggregation and retention were reduced in coronary sinus blood compared with superior vena caval blood in 50 patients with coronary artery disease. A reduced platelet responsiveness at rest may reflect refractoriness after mild stimulation. During pacing-induced angina, platelet function remained unchanged in coronary sinus blood in the 27 men who developed net myocardial lactate production, while ADP-induced aggregation, platelet retention and plasma beta-thromboglobulin levels increased in coronary sinus blood in the 23 men without net lactate production. The results suggest that factors other than ischemia activate platelets in the coronary circulation during stress.

Xanax® 0.5 mg Tablets

alprazolam C IV

THE FIRST TRIAZOLO-BENZODIAZEPINE

Its triazolo ring gives XANAX a structure uniquely different from other benzodiazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

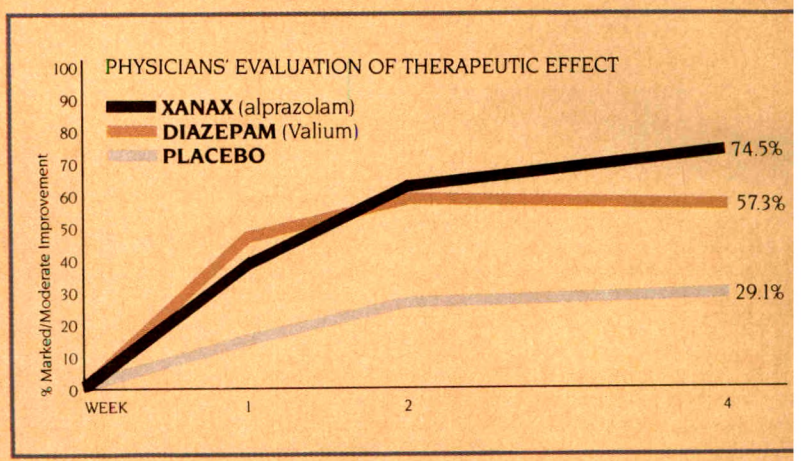
© 1982 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient*, placebo-controlled, multicenter study.*

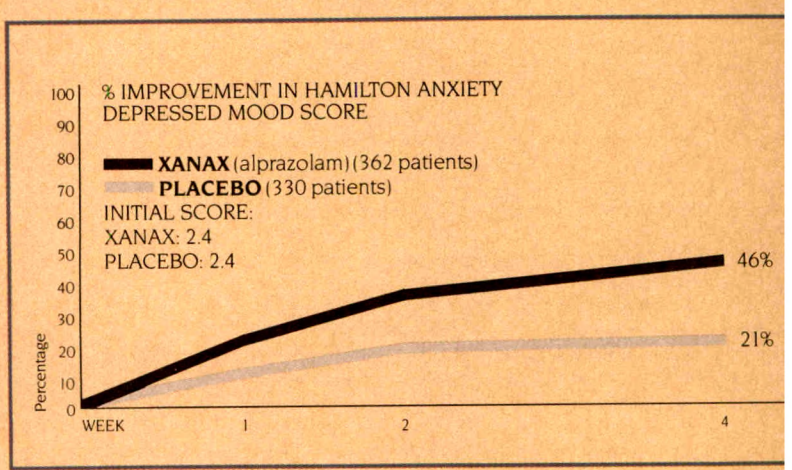


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOM

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam Ⓒ

XANAX® Tablets ©
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests*: Not ordinarily required in otherwise healthy patients. *Drug Interactions*: Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions*: No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility*: No carcinogenic potential or impairment of fertility in rats. *Pregnancy*: See Warnings. *Nonteratogenic Effects*: The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery*: No established use. *Nursing Mothers*: Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use*: Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class*: XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

BS-1

*Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. *J Clin Psychiatry* 42 (9):347-351, 1981.

DIRECTOR OF CARDIOLOGY

MacNeal Memorial Hospital, in conjunction with Ru
Presbyterian St. Luke's Medical Center, is searching
a Director of Cardiology. MacNeal is a 427-bed teachi
hospital located in Berwyn, Illinois, a near-western su
urb of Chicago. We have recently entered into a uniq
joint venture in Cardiology with Rush Presbyterian
Luke's Medical Center. The Director will be in charge
the Cornary Care Unit, the Cardiac Rehabilitation Un
the Heart Station, the proposed Cardiac Catheterizati
Laboratory, and the teaching program. Additional r
sponsibilities will include supervision of 3 hospita
based Cardiologists. The Director and the staff will ha
faculty appointments at Rush Presbyterian St. Luke
Medical Center and will be active members of the Se
tion of Cardiology at MacNeal and at Rush Presbyteria
St. Luke's Medical Center. Applicants should have der
onstrated capabilities in Clinical Cardiology teachir
and administrative duties.

If interested, applicants should send curriculum vitae t
Dr. Joseph Messer or Dr. Larry McLain, MacNeal Mem
rial Hospital, 3249 S. Oak Park Avenue, Berwyn, Illino
60402. MacNeal is an Equal Opportunity/Affirmativ
Action Employer.

470 Clinical Data Versus Noninvasive Testing as an Estimate of Coronary Status

SAMUEL H. BROOKS, JOHN W. ALLEN, W. ALLAN EDMISTON, FRANCIS Y. K. LAU, and DAVID H. BLANKENHORN

The step from coronary angiography to surgery is taken primarily on the basis of the ejection fraction (EF) an number of diseased vessels (NV), taken jointly as coronary status (CS). A quantitative definition of CS was estab lished as a principal component of EF and NV. Estimates of EF, NV and CS were made from the clinical data c 60 patients. Correlations with the actual values were EF 87%, NV 93% and CS 93%. When noninvasive dat were added to this model, the correlations increased to EF 95%, NV 99% and CS 98%. When the clinical dat model was applied to 169 patients, the correlations decreased to EF 77%, NV 71% and CS 74%. CS estimate from clinical data alone was set up as a test for angiography for the 169 patients. This test had a sensitivity c 98% and a specificity of 63%. This study demonstrates the feasibility of using clinical data alone in deciding ar giography.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

477 Role of Catheter Lead System for Transvenous Countershock and Pacing During Electrophysiologic Tests: An Assessment of the Usefulness of Catheter Shocks for Terminating Ventricular Tachyarrhythmias

LAWRENCE E. WASPE, SOO G. KIM, JEFFREY A. MATOS, and JOHN D. FISHER

A single intravascular lead system was used for transvenous countershock, programmed stimulation at the ape of the right ventricle, and ventricular pacing during electrophysiologic tests in 13 patients with inducible su tained ventricular tachycardia (VT) or ventricular fibrillation (VF). Leads were left in place for up to 45 days durir serial tests. Synchronized countershock using energies that patients found tolerable (0.01 to 5 joules [J]) term nated 31 of 50 episodes (62%) of induced VT. Episodes of VT cardioverted with these low energies had long cycle lengths than did other episodes. Among 25 matched pairs of VT episodes, pacing methods were just as e fective as low-energy countershock for VT termination. Higher energies (5 to 30 J) were uniformly effective terminating ventricular flutter and VF. There was no evidence of myocardial injury as a result of shocks up to 3 J. However, patients needed increasing sedation when energy exceeded 0.5 J. This catheter system, includi any implantable unit, may be most useful for slightly higher energy conversions (5 to 30 J) of repeated episod of rapid VT or VF, in which pacing techniques are ineffective.

485 Significance of Prolonged Electrocardiographic Pauses in Sinoatrial Disease: Sick Sinus Syndrome

MEIR MAZUZ and HOWARD S. FRIEDMAN

Eighty-four patients (2.5%) were found to have prolonged (≥2.0 seconds) sinoatrial pauses in a review of Holt recordings. No relation was found between average length of pauses, presence of symptoms or risk of deat Patients who received a pacemaker were older and more likely to be male and to have symptoms. Pacemak recipients were not different from nonrecipients with respect to average longest pause, mechanism of paus underlying heat condition or average time of followup. The survival rate was not improved by permanent pac maker implantation. Thirteen patients who had syncope did not receive a pacemaker; 2 of them had noncardi deaths and none had a subsequent syncopal episode. Ten patients with syncope received a pacemaker; 3 die and 3 survivors continued to complain of dizziness. Of the 37 patients who were asymptomatic at the time of r cording, only 1 patient subsequently had a syncopal episode. Thus, length of sinoatrial pauses correlates poo with symptoms and does not predict sudden death.

490 Cardiac Arrhythmia and Conduction Disturbances During Sleep in 400 Patients With Sleep Apnea Syndrome

CHRISTIAN GUILLEMINAULT, STUART J. CONNOLLY, and ROGER A. WINKLE

Four hundred patients with sleep apnea had a 24-hour Holter electrocardiogram and a polysomnogram dur the late afternoon and nocturnal sleep. Cardiac arrhythmias or abnormalities of conduction were observed in 1 patients. The mean number of apneic events, age, weight and lowest oxygen saturation were not significant fa tors in differentiating the 193 patients from the other 207 patients. Eight patients had unsustained ventricu tachycardia, 43 had sinus arrest that lasted 2.5 to 13 seconds, 31 had second-degree atrioventricular conduct block and 75 had frequent premature ventricular contractions (>2/min). Fifty patients with significant arrhy mias had no arrhythmias after tracheostomy except for premature ventricular contractions.

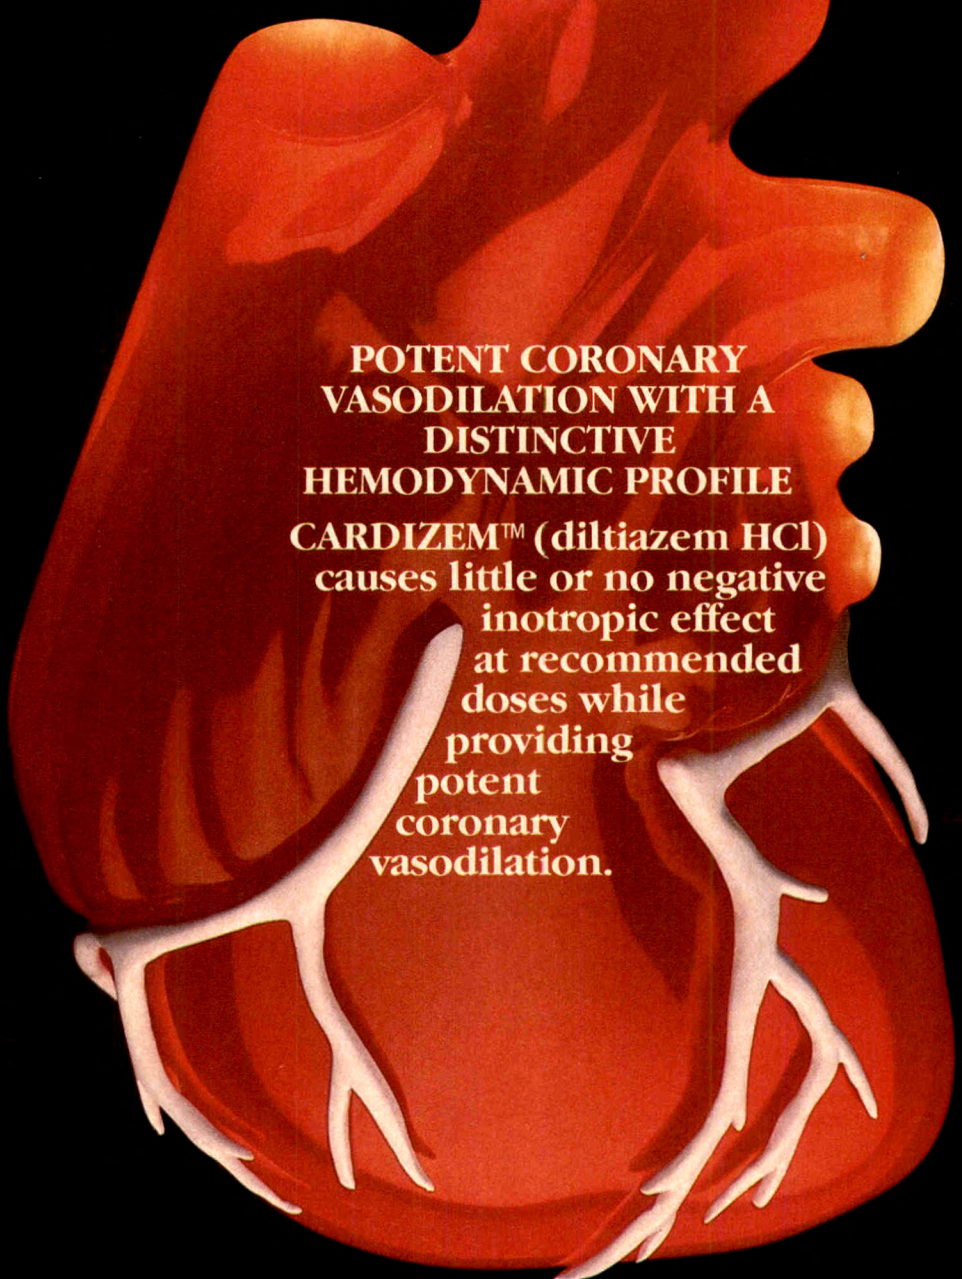
in cardiovascular therapy

CARDIZEM™ (diltiazem HCl)

30 mg and 60 mg tablets

CALCIUM CHANNEL BLOCKADE

from
Marion Laboratories



POTENT CORONARY VASODILATION WITH A DISTINCTIVE HEMODYNAMIC PROFILE

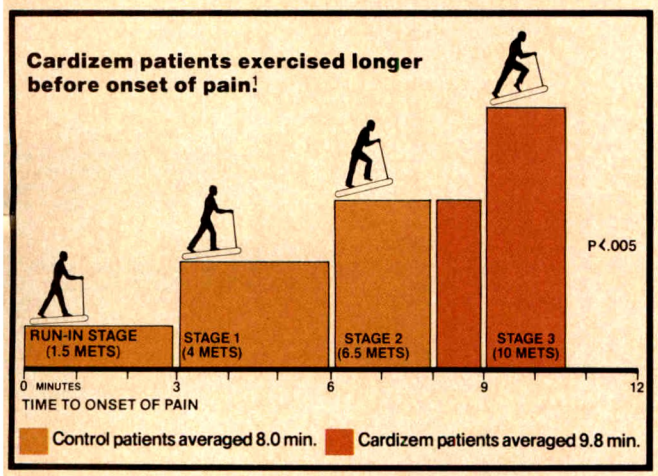
CARDIZEM™ (diltiazem HCl) causes little or no negative inotropic effect at recommended doses while providing potent coronary vasodilation.

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY* WITH A LOW INCIDENCE OF SIDE EFFECTS

Calcium channel blockade with CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

CARDIZEM™ (diltiazem HCl) ALLOWS PATIENTS TO SIGNIFICANTLY PROLONG EXERCISE TOLERANCE, EVEN IN DEMANDING BRUCE PROTOCOL EXERCISE TESTS[1] (n = 15)†



This study is of special significance because patients not only exercised longer but *to the next higher stage* in the Bruce protocol.

A Bruce protocol with a run-in stage was used for all tests. Each stage lasts three minutes.

In other studies, Cardizem produced 41% to 68% reduction of Prinzmetal's variant angina attacks.[2]

Therapy with Cardizem produced a low incidence of side effects.

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with Cardizem have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

Other reactions reported infrequently (less than 1%) are listed in full prescribing information on adjacent page.

†This study is a report from one center in a multicenter study.

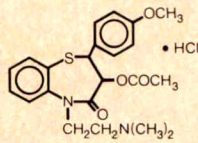
PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (four of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem tid of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to the drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

495 Encainide for Refractory Ventricular Tachyarrhythmia

BRIAN CHESNIE, PHILIP PODRID, BERNARD LOWN, and ERNEST RAEDER

Encainide was studied in 80 patients with a history of malignant ventricular arrhythmia. On the basis of the frequency of arrhythmia, efficacy was judged noninvasively with monitoring and exercise testing in 63 patients and with invasive electrophysiologic testing in 17 patients. Overall, encainide was effective in 34 patients (54%) evaluated noninvasively and in 7 patients (44%) who had electrophysiologic testing. Daily dose and blood levels were equivalent in responders and nonresponders. Toxic side effects occurred in 24 patients (30%), 18 of whom had an aggravation of arrhythmia. Increase in arrhythmia correlated with larger doses and blood levels of the drug. After an average of 21 months, 23 patients continue taking the drug and are free of arrhythmia and adverse effects.

501 Induction of Clinical Ventricular Tachycardia Using Programmed Stimulation: Value of Third and Fourth Extrastimuli

DAVID E. MANN, JERRY C. LUCK, JERRY C. GRIFFIN, JOHN M. HERRE, MARIAN C. LIMACHER, SHARON A. MAGRO, NANCY W. ROBERTSON, and CHRISTOPHER R. C. WYNDHAM

Initiation of ventricular tachycardia (VT) in the electrophysiology laboratory was analyzed in 142 patients who received up to 4 extrastimuli and ventricular burst pacing in the right ventricle. Fifty-three patients had previously documented spontaneous episodes of VT or ventricular fibrillation and 68 patients had no history of VT. Twenty-one patients with a history of sudden death but without documented arrhythmia were excluded from further analysis. In patients with sustained VT, use of third and fourth extrastimuli increased the yield of inducible clinical VT from 37 to 65% compared with use of first and second extrastimuli alone. Clinical VT was not inducible in 10 patients with spontaneous nonsustained VT. Use of third and fourth extrastimuli caused increased induction of nonclinical forms of VT, usually polymorphic and nonsustained, in both patient groups. We conclude that use of third and fourth extrastimuli in the right ventricle improves the yield of inducible clinical VT, but at a cost of increased induction of nonclinical varieties of VT.

507 Hemodynamic Effects of Encainide in Patients With Ventricular Arrhythmia and Poor Ventricular Function

MAGDI H. SAMI, VILMA A. DERBEKYAN, and ROBERT LISBONA

To evaluate the hemodynamic effects of encainide, 19 patients with complex ventricular arrhythmias and poor left ventriclar function (ejection fraction [EF] <45%) underwent gated cardiac scanning before and during steady-state oral encainide therapy. Sixty-three percent had congestive heart failure before they received encainide. Gated scanning was performed 3 days after discontinuing all antiarrhythmic drugs, and was repeated 1 to 2 weeks later on a dose of encainide that was found effective in reducing the frequency of ventricular premature beats by 80% on a 24-hour Holter recording. EFs before and during encainide averaged 22 ± 10% (± standard deviation) and 25 ± 14%, respectively (difference not significant). None of the patients had a decrease in EF of >5% or worsening of congestive heart failure. Other hemodynamic measurements also remained unchanged. Digoxin blood levels measured in 10 patients remained stable during encainide therapy.

CONGESTIVE HEART FAILURE

512 Circulatory Autoregulation in Chronic Congestive Heart Failure: Responses to Head-Up Tilt in 41 Patients

SPENCER H. KUBO and ROBERT J. CODY

To evaluate mechanisms that regulate the response to postural change in patients with chronic congestive heart failure, the hemodynamic and vasoactive hormonal responses to head-up tilt in 41 patients were examined. Peripheral venous pooling was present in only 18 patients and was inversely correlated with baseline pulmonary wedge pressure. Baseline supine hemodynamic indexes of these 18 patients indicated less severe heart failure than in the 23 patients who did not demonstrate venous pooling. Overall, 3 patterns could be identified. Of the 18 patients with venous pooling, 12 maintained many of the elements of normal postural response, with increases in systemic vascular resistance and circulating norepinephrine that maintain blood pressure constant. Six patients did not increase resistance in response to peripheral venous pooling and had major decreases in blood pressure similar to idiopathic orthostatic hypotension. The larger group of 23 patients with more severe failure did not have peripheral venous pooling and, hence, no afferent stimulus for reflex changes. Thus, the hemodynamic and neurohormonal responses to head-up tilt in heart failure are heterogeneous and may be influenced by severity of disease.

VENT. LEAD
AVIUS
Model 263-01
Intermedics Inc.
FREEPORT, TEXAS
DVI DOO VVI

HASSLE FREE PACING

AVIUS™ ELIMINATES MANY PROBLEMS ASSOCIATED WITH CURRENTLY AVAILABLE DUAL CHAMBER PRODUCTS AND OPTIMIZES PACING PERFORMANCE.

No more problems with:
Asynchrony
Crosstalk
Retrograde Conduction
Complex ECG's

AVIUS simply delivers good, reliable dual chamber performance. It's no wonder you can prescribe it with confidence.

AVIUS has more flexible programming capabilities than any other DVI pacemaker currently available.
With more prescription combinations to help you tailor pacing operation to individual patient needs.

AVIUS also has fewer post-op problems.
AVIUS is the DVI mode A-V sequential pacemaker that is inherently immune to many clinical complications experienced with other dual chamber products. Immune to the kinds of problems that force you to change modes.

AVIUS makes patient follow-up easier.
Interpretation of ECG recordings is less complex than with other more complex dual chamber products. And AVIUS offers you transtelephonic telemetry.

AVIUS is reliable.
Its circuitry is based on time-proven Intermedics circuitry. And it has the largest battery capacity of any available DVI pacemaker.

AVIUS restores A-V synchrony **thus increasing cardiac output because it is a dual chamber pacing system.**

AVIUS practically eliminates pacemaker syndrome.

AVIUS. The pacemaker you can count on for hassle free pacing.
From Intermedics, the people with more clinical experience with dual chamber devices than any other company. For more information, contact your nearest Intermedics representative, or call us toll-free at 1-800-231-2330 (in Texas dial 1-800-392-3726).

Intermedics Inc.®

Our Business is Life.®

P.O. Box 617
Freeport, Texas 77541

INDICATIONS FOR USE: Implantable cardiac pulse generators may be indicated for long-term treatment of impulse formation or conduction disorders resulting in symptomatic bradyarrhythmias, and heart block unresponsive to drug therapy.

A-V sequential pacing is specifically indicated for treatment of conduction disorders that require restoration of both rate and atrio-ventricular synchrony. A-V sequential pacing may also be indicated for patients with extensive myocardial infarction with A-V block and sinus bradycardia.

CONTRAINDICATIONS AND SIDE EFFECTS: There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. Body rejection phenomena, local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

PRECAUTIONS: See the "Cautionary notes" section of the Physicians Manual for the Intermedics cardiac pluse generator to be implanted. Discussion includes Possible Complications, Environmental Hazards (electrocautery, diathermy, defibrillation, therapeutic radiation, home appliances, and industrial and special environments), and Effects of Drugs.

VAVULAR HEART DISEASE

519 Accuracy of Evaluation of the Presence and Severity of Aortic and Mitral Regurgitation by Contrast 2-Dimensional Echocardiography

CHERYL L. REID, DAVID T. KAWANISHI, CHARLES R. McKAY, URI ELKAYAM, SHAHBUDIN H. RAHIMTOOLA, and P. ANTHONY N. CHANDRARATNA

Contrast 2-dimensional (2-D) echocardiography was performed during cardiac catheterization to compare the technique with cineangiography in evaluating the presence and severity of aortic (AR) and mitral regurgitation (MR). A physiologic solution was injected through the intracardiac catheter while echocardiographic recordings were obtained in multiple views. AR was evaluated in 35 patients; sensitivity, specificity and predictive accuracy was 100% for detection of AR by 2-D echocardiography. Severity of AR based on visual assessment by both 2-D echocardiography and cineangiography correlated with $r = 0.998$. MR was evaluated in 59 patients. Sensitivity for detection of MR by 2-D echocardiography was 84% and specificity 89%. Severity of MR by both methods correlated with $r = 0.998$. Contrast 2-D echocardiography for the evaluation of the presence and severity of AR and MR is both sensitive and specific. Use of 2-D echocardiography in the cardiac catheterization laboratory should be of greatest value when the use of cineangiography is limited by the dose of contrast medium, radiation or technical problems.

525 Two-Dimensional Echocardiographic Determination of Right Atrial Emptying Volume: A Noninvasive Index of Quantifying the Degree of Tricuspid Regurgitation

NICHOLAS L. DePACE, JIAN-FANG REN, MORRIS N. KOTLER, GARY S. MINTZ, DEMETRIOS KIMBIRIS, and PETER KALMAN

Using a computerized light-pen method to trace the right atrial (RA) border during systole and diastole in the apical 4-chamber view, single-plane volume determinations were calculated in 10 normal subjects (Group I), 18 patients with atrial fibrillation (AF) and no tricuspid regurgitation (TR) (Group II), 14 patients with mitral stenosis and mild TR (Group IIIa), and 8 patients with mitral stenosis and severe TR (Group IIIb). TR was quantitated as absent, mild or severe by contrast right ventriculography. The mean RA emptying volume, which equals RA end-systolic volume − RA end-diastolic volume, was 15 ± 5.0 for Group I, 18 ± 3.0 for Group II, 30 ± 8.0 for Group IIIa and 72 ± 25 for Group IIIb. All 8 patients with severe TR had an RA emptying volume >40 ml, compared with none of the 14 patients with mild TR ($p < 0.001$). Thus, in patients with mitral stenosis, RA emptying volume is useful in separating severe TR from mild TR.

530 Influence of Volume Loading on Intraoperative Hemodynamics and Perioperative Fluid Retention in Patients With Valvular Regurgitation Undergoing Prosthetic Replacement

J. GILBERT STONE, PAUL F. HOAR, and HOSHANG J. KHAMBATTA

Preload and afterload were controlled intraoperatively in 2 groups of patients with valvular regurgitation and congestive heart failure to determine the effect of fluid loading on weight gain and subsequent recovery. Sixteen patients were given 1 liter of crystalloid with nitroprusside infused at 1 μg/kg/min and 16 received 4 liters of crystalloid with nitroprusside at 4 μg/kg/min. Arterial and filling pressures were kept the same in both groups. Heart rate and vascular resistance became significantly lower and cardiac index and stroke volume significantly higher in the fluid-augmented group. The transition to cardiopulmonary bypass was smoother for the fluid-augmented patients. Mean weight gain at surgery was equal in the 2 groups (3 kg). For the first 2 postoperative days, body weight remained unchanged, and thereafter, both groups lost weight at a rate of 0.6 kg/day. Thus, a modest amount of operative weight gain in these patients is inevitable, benign and independent of the volume of prebypass infused fluid.

534 Mitral Valve Prolapse Syndrome: Analysis of 62 Patients Aged 60 Years and Older

ALBERT J. KOLIBASH, CHARLES A. BUSH, MARY BETH FONTANA, JOSEPH M. RYAN, JAMES KILMAN, and CHARLES F. WOOLEY

Sixty-two patients 60 to 81 years of age were diagnosed as having mitral valve prolapse on the basis of classic auscultatory, echocardiographic and angiographic findings. These patients presented in a clinically predictable pattern with symptoms of disabling chest pain, arrhythmias and the presence of a murmur of mitral regurgitation with congestive heart failure. Twenty patients presented with disabling chest pain, 7 of whom had significant coronary artery disease. The presence of coronary artery disease could not be detected on the basis of history or noninvasive laboratory studies alone. Sixteen patients with palpitations had a broad spectrum of rhythm disor-

The one on the left has three times more adhesive surface.

Nitro-Dur™ (nitroglycerin) Transdermal Infusion System 10cm^2, on the left, has three times the adhesive surface area of the comparable Ciba product (5 mg). Nitro-Dur 20 cm^2 provides twice the adhesive surface area as the comparable Ciba product (10 mg). The wide adhesive strip assures good matrix-to-skin contact and helps keep the system sealed and in place. It also separates easily from the backing, for easy opening and application. By contrast, the Ciba product has minimal outside adhesion. The adhesive lies primarily on the central surface through which the drug must pass.

A wide adhesive strip. It's just one reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing a range of dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies using healthy volunteers,[1] transdermal absorption of nitroglycerin from Nitro-Dur achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Detectable plasma levels were attained within 30 minutes after application of the unit, and were still detectable 30 minutes after removal of the unit.

INDICATIONS AND USAGE: This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

THE BURDICK CORPORATION, MILTON, WISCONSIN 53563, TOLL-FREE 800-356-0701, IN WISCONSIN 608-868-7631

ders, including supraventricular and ventricular arrhythmias. Two patients in this group had prehospital sudden death and 2 others had evidence of systemic embolization. Twenty-six patients presented with mitral regurgitation and congestive heart failure, 21 of whom required mitral valve surgery and were found to have enlarged, floppy mitral valves with redundant leaflets at the time of surgery. Histologic examination showed extensive myxomatous changes throughout the valve leaflets. Thus, mitral valve prolapse was identified in this elderly group of patients who presented with clinical findings similar to those seen in the younger population with mitral valve prolapse.

540 Valve of Isometric Exercise Testing During Cardiac Catheterization in Mitral Stenosis

HEIKKI V. HUIKURI and JUHA T. TAKKUNEN

The isometric handgrip exercise test was performed during preoperative diagnostic catheterization by 28 patients with mitral stenosis (MS). Eighteen patients who underwent mitral valve surgery were recatheterized and reevaluated clinically 12 months after surgery. Sixteen patients whose mitral valve pressure gradient increased >4 mm Hg during isometric exercise had an increase in peak systolic pressure/end-systolic volume ratio ($p < 0.001$) and their ejection fraction remained unchanged (group A). Twelve patients whose mitral valve pressure gradient decreased or increased <4 mm Hg had a decrease in ejection fraction ($p < 0.001$), and their peak systolic pressure/end-systolic volume ratio remained unchanged during exercise (group B). In the total group, a correlation existed between the change in mitral pressure gradient and the changes in measures of left ventricular (LV) function during exercise. The patients in group A had a significant improvement in symptoms and exercise tolerance after surgery and the patients in group B had only minimal symptomatic improvement and their exercise tolerance did not improve after surgery. Thus, the change in mitral valve pressure gradient during isometric exercise appears to reflect the LV response to exercise.

CARDIOMYOPATHY

544 Influence of Verapamil Therapy on Left Ventricular Performance at Rest and During Exercise in Hypertrophic Cardiomyopathy

PETER HANRATH, MICHAEL SCHLÜTER, FRANK SONNTAG, JÖRG DIEMERT, and WALTER BLEIFELD

The effects of chronic high-dose verapamil treatment on resting and exercise hemodynamics in patients with hypertrophic cardiomyopathy are presented. Systolic cardiac performance in terms of stroke volume index improved significantly in these patients at rest as well as during maximal symptom-limited exercise. The main factors responsible for this improvement are believed to be the vasodilative effect of verapamil and the reduction in heart rate. Verapamil-induced improvement of diastolic cardiac performance is shown by a significant decrease of end-diastolic pulmonary artery pressure during exercise.

CONGENITAL HEART DISEASE

549 Changing Results and Concepts in the Surgical Treatment of Double-Outlet Right Ventricle: Analysis of 137 Operations in 126 Patients

GIAN PICCOLI, ALBERT D. PACIFICO, JOHN W. KIRKLIN, EUGENE H. BLACKSTONE, JAMES K. KIRKLIN, and LIONEL M. BARGERON, Jr.

One hundred thirty-seven operations (98 repairs, 23 preliminary operations and 16 palliative operations for uncorrectable malformations) were performed for double-outlet right ventricle (DORV) from January 1967 through July 1982, with 36 hospital deaths (26%). Incremental risk factors for death after 42 "classic" DORV repairs included young age, type of repair and era. In the current era (1978 through July 1982), 1 of 19 (5%) died (70% confidence limits 0.7 to 17%), with the risk of young age evident only under age 3 months. Among 28 repairs of Taussig-Bing hearts, 11 patients (39%) died; the mortality rate has not improved over time. Repair that included venous switching was the only risk factor. Of 24 patients repaired, having normally positioned or D-malposed great arteries and noncommitted ventricular septal or complete atrioventricular canal defects, 7 died, 1 among the 11 repairs in the current era. Four with L-malposition underwent repair, with no deaths. Thus current results of repair are good, even in infants, except in patients with Taussig-Bing hearts. In these patients, repair without venous switching is recommended.

for many post-MI patients...

Cardio-protective.

Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy, exacerbation of angina and, in some cases, myocardial infarction have occurred after **abrupt** discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

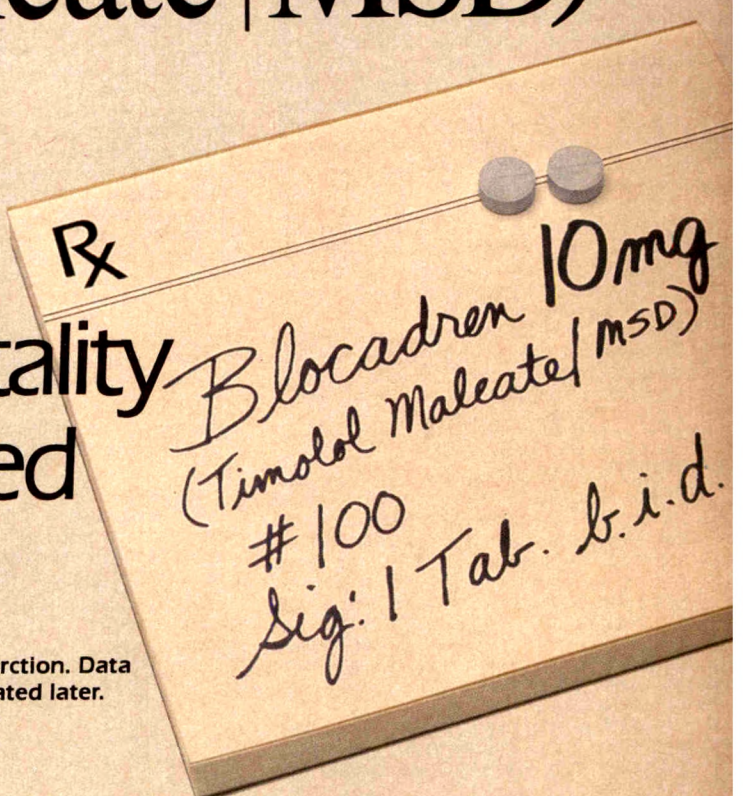
Blocadren®
(Timolol Maleate | MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients

Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.



disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

For a Brief Summary of Prescribing Information, please see next page of this advertisement.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: *Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

CONTENTS

555 Surgical Anatomy of Double-Outlet Right Ventricle—A Reappraisal

ROBERT H. ANDERSON, ANTON E. BECKER, BENSON R. WILCOX, FERGUS J. MACARTNEY, and JAMES L. WILKINSON

The morphology of hearts in which more than half of both arterial valves connect to the right ventricle is reevaluated with surgical considerations. The categorization of these hearts into groups according to the relation of the arterial trunks allows the site of the ventricular septal defect to be inferred. The ventricular septal defect is almost always cradled between the limbs of the septomarginal trabecula; the posteroinferior border may be muscular or membranous. The defect is usually subaortic, sometimes doubly committed and rarely noncommitted in hearts with normally related great arteries. When the great arteries are parallel with the aorta to the right, the defect is usually subpulmonary and rarely doubly committed. The defect is either subaortic or doubly committed when the aorta is to the left of the pulmonary trunk. Cross-sectional echocardiography should provide accurate diagnosis of the anatomy for the surgeons.

560 Percutaneous Balloon Pulmonary Valvuloplasty

ZUHDI LABABIDI and JIUNN-REN WU

Percutaneous balloon pulmonary valvuloplasty (BPV) was performed in 18 consecutive patients with valvular pulmonary stenosis. The patients were aged 11 months to 19 years. The balloons were 12 or 15 mm in diameter and required 100 to 120 pounds/square inch to achieve full inflation when positioned across the stenotic pulmonary valves. Each inflation lasted 10 seconds. Pulmonary valve gradients (ΔP) and cardiac outputs were measured before and 15 minutes after BPV. Significant decrease in ΔP occurred without a decrease in cardiac output. The prevalvuloplasty ΔP dropped from 81 ± 31 to 23 ± 11 mm Hg after BPV ($p < 0.01$). The right ventricular pressure dropped from 106 ± 31 to 50 ± 12 mm Hg ($p < 0.01$). No pulmonary regurgitation was noted. BPV may offer an alternative method for treating pulmonary stenosis.

563 Hemodynamic Responses to Ergometer Exercise in Children and Young Adults With Left Ventricular Pressure or Volume Overload

BRUCE S. ALPERT, DARLENE M. MOES, ROBERT H. DURANT, WILLIAM B. STRONG, and NADINE L. FLOOD

Exercise tests were performed in 137 children and young adults with left ventricular (LV) pressure or volume overload and their data were compared with those from 405 healthy control subjects. By analysis of covariance, the effects of age, race, sex and body surface area were removed. The responses to cycle ergometer stress testing in the patients differed from responses in control subjects for most of the variables studied. The patients with LV volume overload had slightly more impaired responses. The data from the present study do not support those from studies of smaller groups of patients with aortic stenosis that indicated that any exercise variable was predictive of the severity of the LV-to-aorta gradient.

568 Aortic Valve Replacement in Childhood: Evaluation of Left Ventricular Function by Electrocardiography, Echocardiography and Graded Exercise Testing

GEORGE S. BISSET III, RICHARD A. MEYER, STEPHEN S. HIRSCHFELD, FREDERICK W. JAMES, DAVID C. SCHWARTZ, and SAMUEL KAPLAN

Noninvasive assessment of pre- and postoperative left ventricular function was performed in 15 children who survived aortic valve replacement. Electrocardiography, M-mode echocardiography and graded exercise testing were performed. Patients were grouped according to the dominant lesion preoperatively (aortic stenosis or aortic regurgitation). After aortic valve replacement in patients with aortic stenosis, left ventricular mass remained increased. There was echographic evidence that left ventricular afterload decreased, as demonstrated by a return to normal of the left ventricular shortening fraction. Working capacity and systolic blood pressure responses have remained abnormal for up to 12 years. In patients with aortic regurgitation, the left ventricle remained dilated postoperatively. Septal motion was also abnormal. All patients in this group had ST-segment depression during maximal exercise postoperatively. Aortic valve replacement does not represent curative surgery in the pediatric age group. Most children continue to have evidence of abnormalities of left ventricular performance.

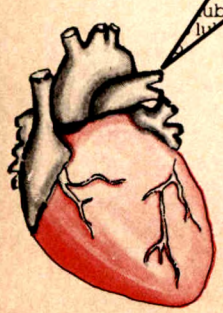
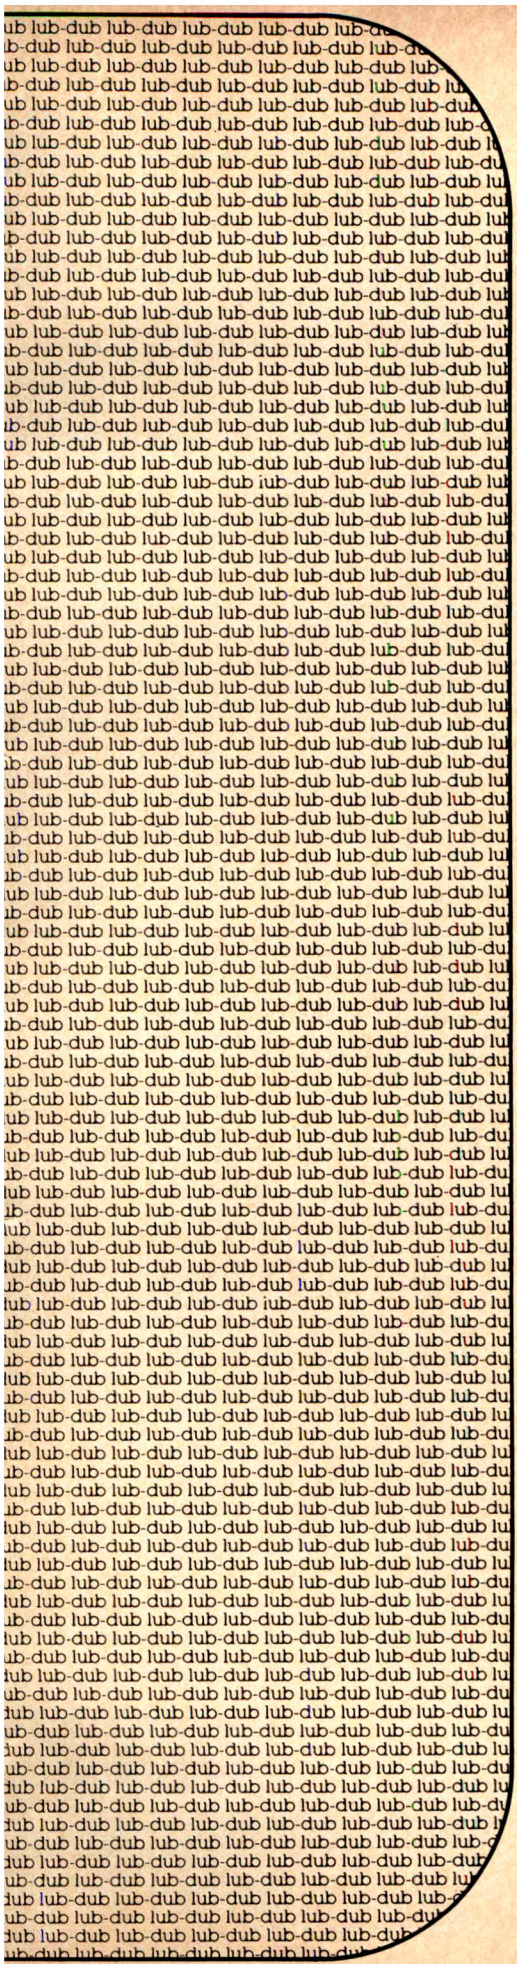
25,000,000,000

beats later

and counting





Norpace®
(disopyramide phosphate)
100-mg and 150-mg capsules

The brand that counts most often in control of dysrhythmia

Five years on the market...7 million patient-months of experience...more than 7 million prescriptions dispensed...and the beat goes on.

Norpace® CR
(disopyramide phosphate)
controlled release
100-mg and 150-mg capsules

True 12-hour dosing convenience

Now, with Norpace CR, you can add true 12-hour dosing convenience to the established efficacy of Norpace...with no increase in cost to the patient.

As a consequence of the negative inotropic properties of disopyramide phosphate, adequate cardiac function must be established and maintained. Norpace/Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac dysrhythmia.

The leading branded antiarrhythmic agent...Norpace

SEARLE

Please see the next page for a brief summary of the complete prescribing information.

Norpace®
(disopyramide phosphate) 100-mg and 150-mg capsules

Norpace® CR controlled release
(disopyramide phosphate) 100-mg and 150-mg capsules

the leading branded antiarrhythmic agent

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs for overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

Cardiology Unit, University of Vermont

Full-time position in Department of Medicine. Major responsibilities include Director of Coronary Care unit, teaching of acute cardiac care, special skills required in either cardiac catheterization, cardiac electrophysiology or nuclear cardiology and an ability to develop fundable independent research programs is essential. Applicants must be Board certified or eligible in Cardiology and possess a minimum of 3 years training in Cardiology. Send inquiries with CV by October 1 to Dr. Arthur M. Levy, Cardiology Unit, Medical Center Hospital of Vermont, Burlington, VT 05401. The University of Vermont is an Affirmative Action Employer. Women and minorities are encouraged to apply.

CARDIOLOGIST: To join a group in Northeastern Pennsylvania. Expertise Cardiac Catheterization Mandatory. Send C.V. and Date available to start to Box 280, The American Journal of Cardiology, 875 Third Avenue, New York, NY 10022.

The 2nd International Course of Renal Transplantation will be held in Barcelona (Spain) at the Palacio de Congresos on the 12th, 13th, 14th and 15th of December, 1983 directed by Drs. Jose Mª Gil-Vernet, Antonio Caralps, J. Vives, J. Andreu and A. Brulles.

The Course will address the most significant medical and immunological aspects of renal transplantation. The Course will offer scientific lectures, practical courses in immunology and actual surgical operations broadcasted in colour T.V.

Secretary: F. Oppenheimer. Unidad de Trasplante Renal. Hospital Clínico. Casanova 143. Barcelona-36. (Spain).

CONTENTS

573 Double-Inlet Left Ventricle With Rudimentary Right Ventricle and Ventriculoarterial Concordance

ROBERT H. ANDERSON, CORA C. LENOX, JAMES R. ZUBERBUHLER, SIEW Y. HO, AUDREY SMITH, and JAMES L. WILKINSON

Seven hearts with double-inlet left ventricle, rudimentary right ventricle and ventriculoarterial concordance were studied. In 5 hearts, 2 atrioventricular valves were present and 2 hearts had a common atrioventricular valve. The rudimentary right ventricle was obliquely situated on the anterior surface of the left ventricle in 6 cases. One heart had the rudimentary right ventricle in the left-sided position. Conduction tissue studies were performed in 2 hearts. In 1, the distribution was as expected in double-inlet left ventricle, but a different pattern was seen in the other case. These conduction tissue findings are discussed in light of options for surgical repair. The anatomic findings of the study are related to the likely modes of presentation and differential diagnosis. It is suggested that the term "single ventricle" should not be used to describe these hearts because they do possess 2 ventricular chambers.

578 Pulmonary Vascular Development: Normal Values of Peripheral Vascular Structure

SHEILA G. HAWORTH and ALISON A. HISLOP

Uninjected postmortem normal lung tissue from 49 children aged 1 hour to 14 years were studied using quantitative morphometric techniques to assess arterial size, number and muscularity, particularly in the respiratory region of lung. The normal values in this report provide a basis for the evaluation of lung biopsies in childhood.

MISCELLANEOUS TOPICS

584 Biventricular Function in Sickle-Cell Anemia: Radionuclide Angiographic and Thallium-201 Scintigraphic Evaluation

BRUNO V. MANNO, EDWARD R. BURKA, A-HAMID HAKKI, CATHERINE S. MANNO, ABDULMASSIH S. ISKANDRIAN, and ANN MARIE NOONE

The left ventricular (LV) and right ventricular (RV) function at rest and during exercise were evaluated in 10 patients with sickle-cell anemia (SCA). The LV ejection fraction (EF) was normal in 9 patients at rest and in all 10 patients during exercise, whereas only 2 patients had a normal RVEF at rest and during exercise. Rest thallium-201 images from 9 patients showed abnormal RV function in 8. Thus, in adult patients with SCA, LV function is normal, whereas RV function is abnormal in most patients, most likely because of pulmonary vasoocclusive complications of the disease.

588 Effects of Negative Pleural Pressure on Left Ventricular Hemodynamics

SHELDON A. MAGDER, SAMUEL LICHTENSTEIN, and ALLAN G. ADELMAN

Because negative pleural pressures could theoretically affect left ventricular (LV) function, the hemodynamics of the Mueller maneuver (inspirations against closed airways) was studied in 11 patients. This procedure produced an immediate decrease in aortic and left atrial pressures. However, transmural aortic and left atrial pressures (relative to atmosphere) increased markedly. Similar changes occurred during spontaneous breathing. These changes are best explained by right ventricular interference with LV function and impedance to LV ejection by the negative pleural pressure.

METHODS

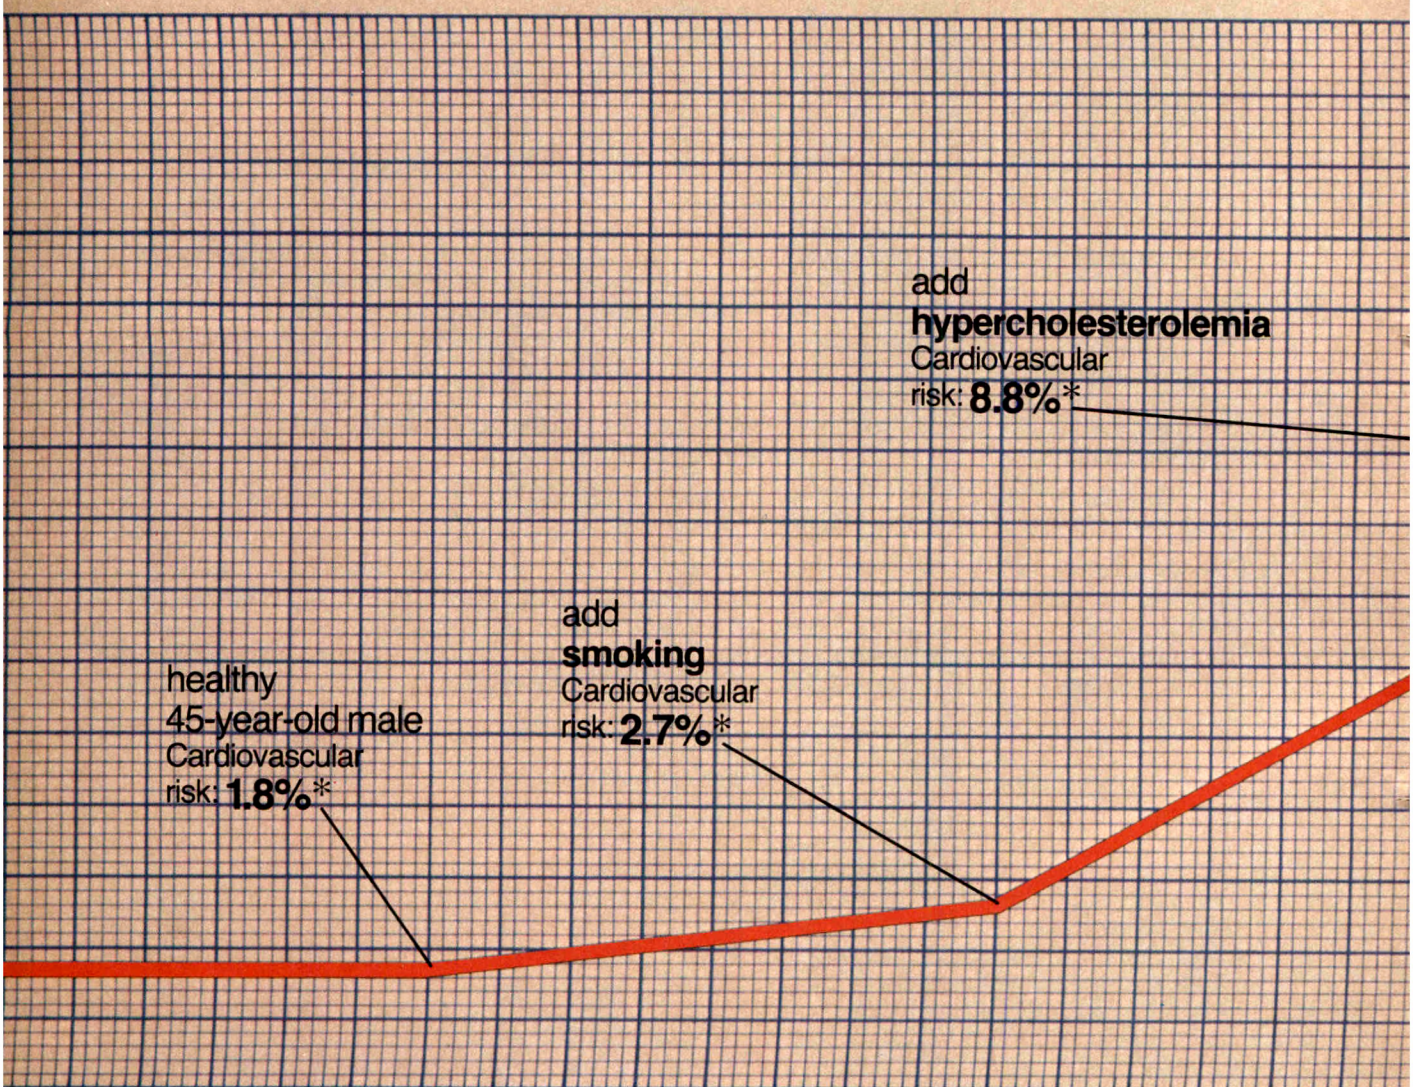
595 Effects of Posture and Respiration on Body Surface Electrocardiogram

DAVID J. SUTHERLAND, DAVID D. McPHERSON, C. ANNE SPENCER, C. SUSAN ARMSTRONG, B. MILAN HORACEK, and TERRENCE J. MONTAGUE, *With the technical assistance of* SHARON A. BLACK *and* SUSAN M. RIGBY

Body surface electrocardiograms (ECGs) were recorded in 36 normal subjects during cyclic respiration in the supine and upright positions, and at static end-tidal inspiration, functional residual capacity, total lung capacity and residual volume. Torso distributions of the time integral of the P wave and QRS and ST segments were determined with a 120-lead electrode array. Changes in ECG distributions were assessed by difference-mapping techniques and the root-mean-square index of variability. Position change from supine to upright and maximal inspiration were associated with inferior spatial shifts of P-wave and QRS torso distributions. Tidal volume respiration was associated with very little change in spatial appearances. The greatest root-mean-square variability occurred between maps at the end points of maximal respiration and was least for tidal volume respiration, with position change having an intermediate degree of variability—in relative terms, P-wave variability > ST > QRS

Continued on page A54

In hypertensive patients:

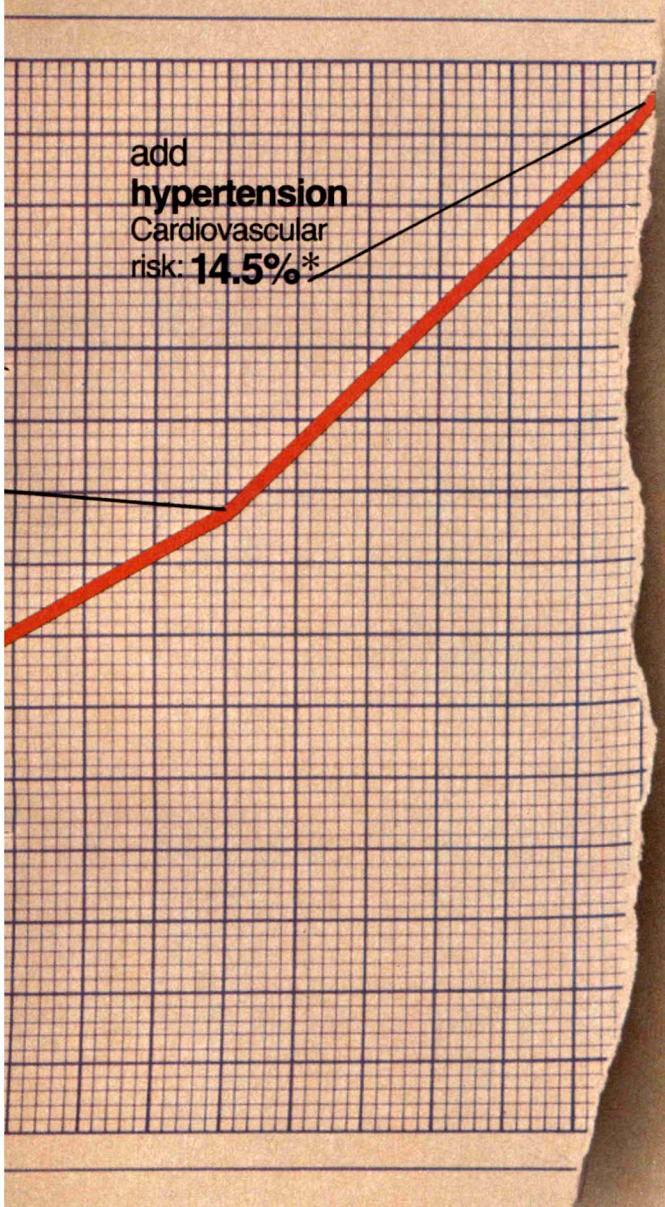


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1mg, 2mg, 5mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

BIOTRONIK

Pacers in a class of their own™

Whichever way you look at it,

it's the smallest

BIOTRONIK

Pacers in a class of their own™

On one hand even less pacemaker

- Smallest, thinnest pacemaker available (57 × 41 × 8.8 mm)
- Lightweight (only 37 g)
- Anatomically, optimized shape

On the other hand an even larger scope of therapy

- Suitable for atrial or ventricular stimulation
- All clinically relevant parameters are programmable over a wide range
- A selection of high output voltages for the management of exit blocks
- Constant output voltage even during battery end-of-life; the output amplitude remains at the programmed value
- The entire pacemaker program can be interrogated and displayed in one complete block – not split into single parameters – by using the EPR 500 Programmer. A program printout is also supplied upon request.

BIOTRONIK pacemakers combined with the various BIOTRONIK active and passive fixation leads provide integrated pacing systems with the assurance of maximum reliability since all parts match one another and enable you to decide which system best suits the needs of each individual patient.

segments. Thus, resting tidal volume respiration has little effect on body respiration and posture change may, however, be associated with substa in body surface potential map distributions, and their effects should be co volve either factor.

601 An Ambulatory Ventricular Function Monitor: Validation and Prelimina

RICHARD A. WILSON, PAUL J. SULLIVAN, RICHARD H. MOORE, JA NATHANIEL M. ALPERT, CHARLES A. BOUCHER, KENNETH A. McK

A device for the continuous measurement of left ventricular (LV) function ment consisted of 2 arrays of radiation sensitive cadmium telluride detecto left ventricle and lung by a vest-like garment (hence the name VEST). Th cluded analog-to-digital converters, a battery pack, microprocessor and back pack. Data generated by the VEST, including the digitized aver counts/13 ms in each radiation detector, and time since commencement a cassette tape recorder every 2 minutes for subsequent analysis. At the blood pool imaging, the VEST was positioned and worn by the subjects wh ing. The correlation of ejection fraction calculated independently from th was >0.95. The inter-record reproducibility of the ejection fraction measu was <3%.

607 Hydrogen Peroxide Contrast Echocardiography

F. ANDREW GAFFNEY, JUI-CHIN LIN, RONALD M. PESHOCK, LARRY B

There are several echocardiographic contrast agents, but their unreliability vious studies suggest that dilute hydrogen peroxide (H_2O_2) is a safe intrav in contrast echocardiography. To obtain dense opacification reliably, H_2O_2 0.2 μm Millipore filter and diluted with heparinized saline solution to mak blood was withdrawn from an intravenous needle into a syringe containing the contents injected. Studies in dogs, normal adults and 36 patients with dense, sustained opacification with no complications. In vitro mixture of H_2 or plasma produced only a few microbubbles, while addition to whole suggesting that microbubble formation is due to oxygen produced by leuko cardiography is simple and inexpensive, and reliably provides dense, sustai nificant advantages over currently used agents. Caution should be exercis hypertension or large right-to-left shunts because little clinical experienc tients.

EXPERIMENTAL STUDIES

610 Effect of Coronary Reperfusion on Myocardial Hemorrhage and Infarct

CHARLES S. ROBERTS, FREDERICK J. SCHOEN, and ROBERT A. KL

Early coronary reperfusion for treatment of acute myocardial infarction is a result in hemorrhagic infarction. The effect of hemorrhage on the healin reperfusion is unknown, but could be detrimental. To compare repair of ischemic infarcts, 2 coronary arteries were occluded in 14 anesthetized d reperfused. Either 1 or 14 days later, samples from the center of the infarct analyzed for hemoglobin (Hb), creatine kinase (CK) and hydroxyproline co days after coronary occlusion, the myocardium was studied histologically was present in all reperfused infarcts at 1 day; hemoglobin content was 8 10 ± 2 mg/g in permanently ischemic infarcts, but was highest in reperfus versus permanently ischemic infarcts). CK content in reperfused infarcts an similarly depressed (4 ± 2 and 7 ± 1 IU/mg protein, compared with 30 ± 5 p <0.05). At 3 days, polymorphonuclear leukocyte infiltration was less pro permanently ischemic infarcts. At 14 days, hydroxyproline levels were sim μg/mg) and permanently ischemic infarcts (10.7 ± 1.9 μg/mg), and higher μg/mg). Thus, intramyocardial hemorrhage occurs early in reperfused infa nently ischemic infarcts, and is associated with an altered early granulocyte lagen formation.

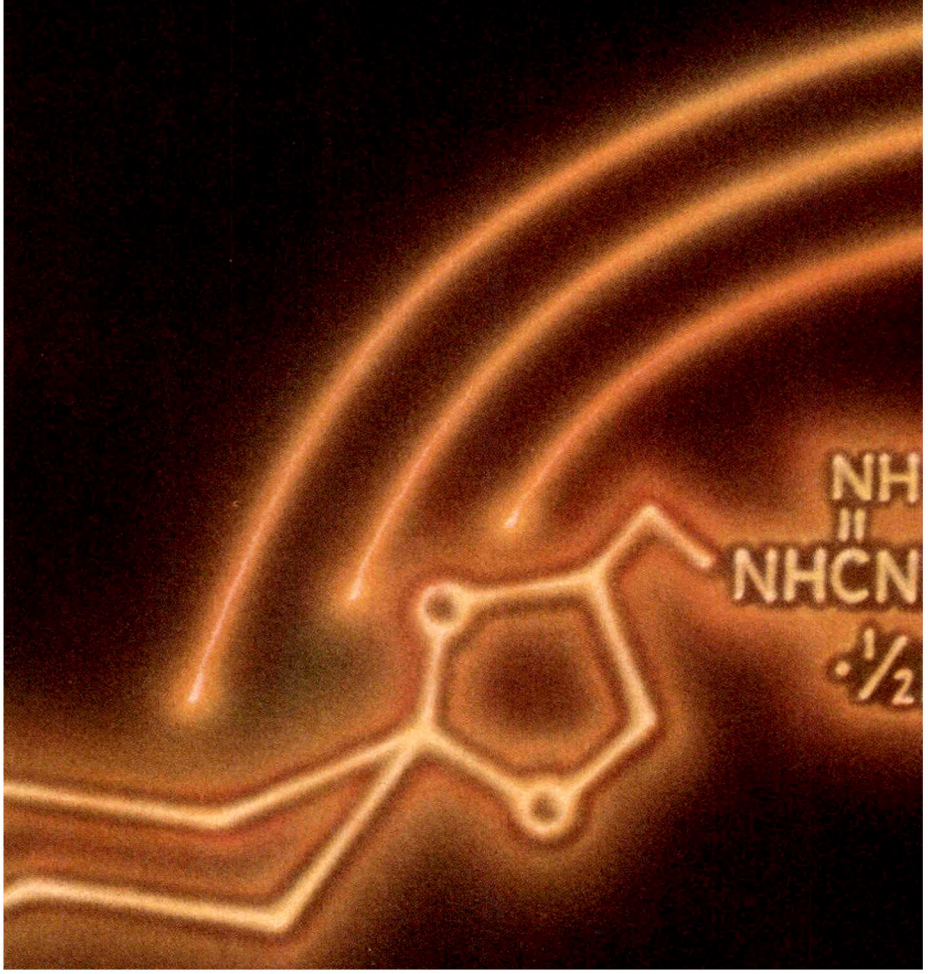
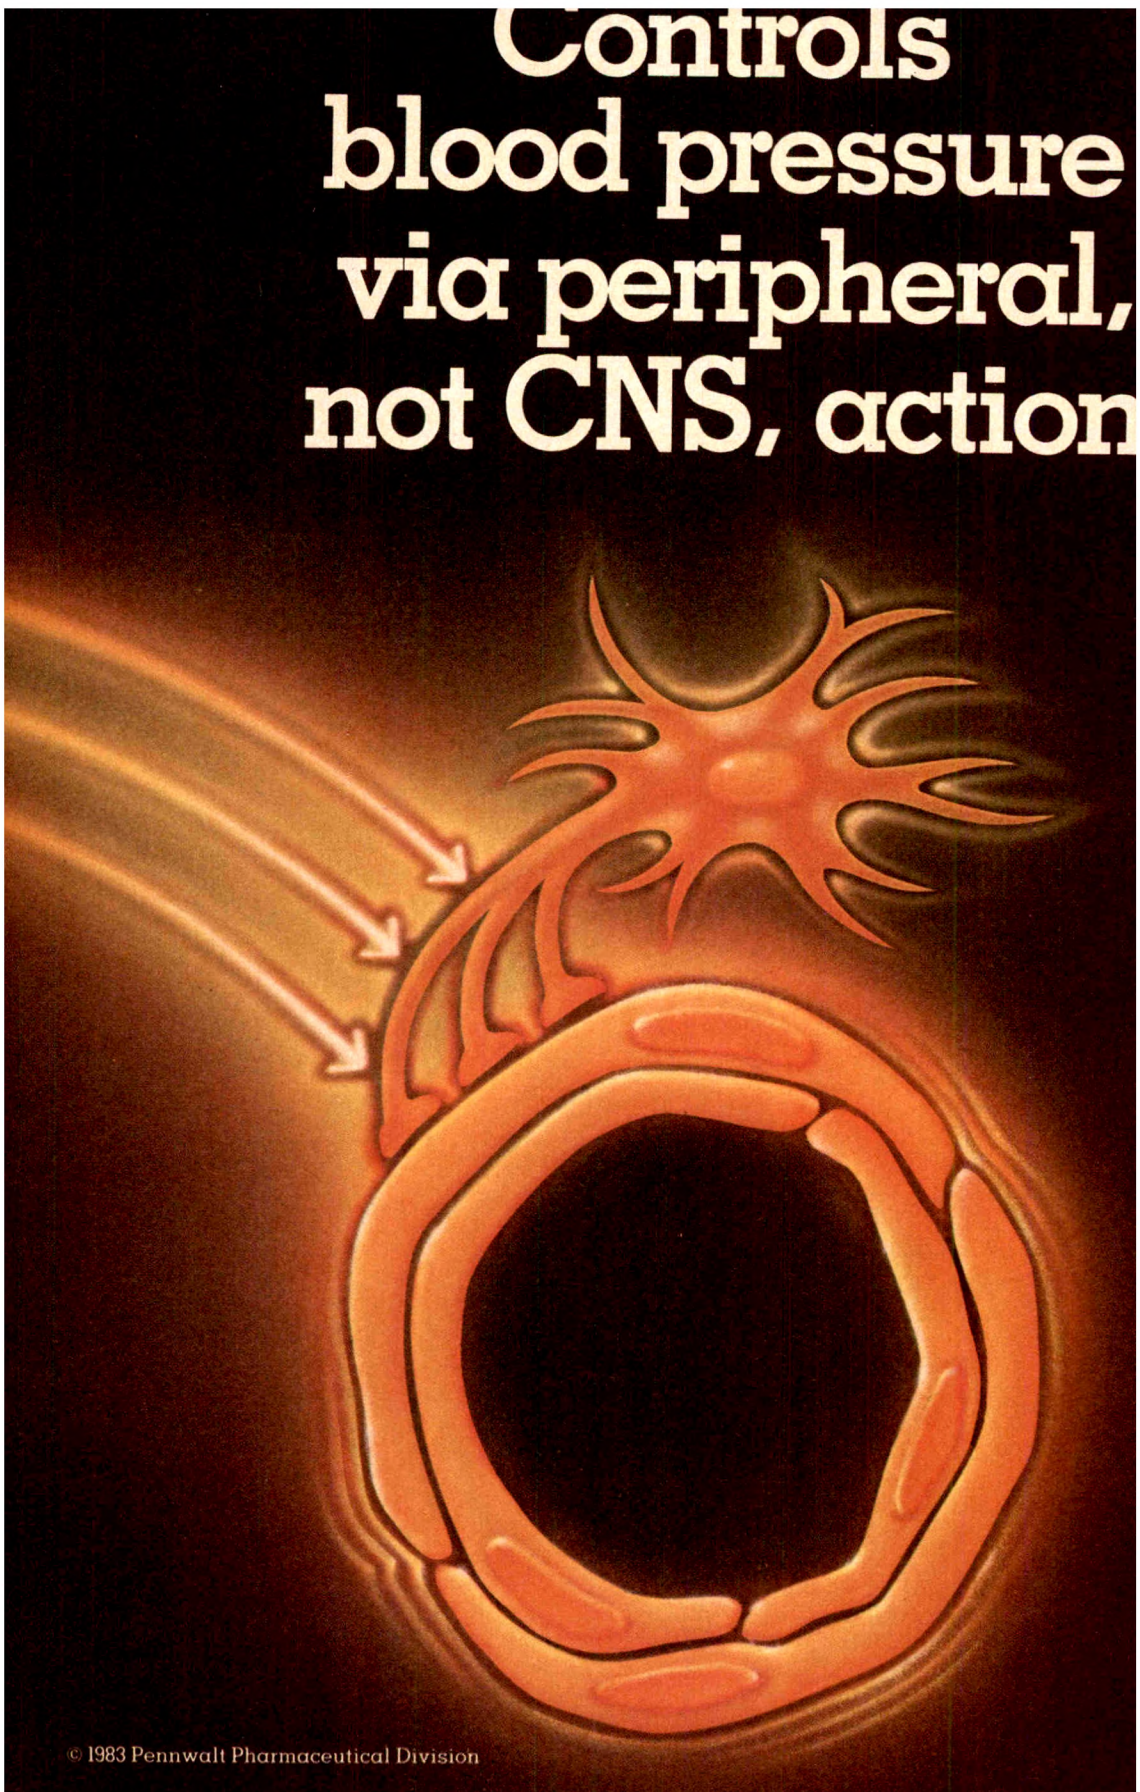
Hylorel® 10 & 25
Tablets
(GUANADREL SULFA





Controls
blood pressure
via peripheral,
not CNS, action
© 1983 Pennwalt Pharmaceutical Division

HYLOREL: A New Peripheral Sympathetic Inhibitor

HYLOREL controls blood pressure via peripheral, not CNS, action... allowing relaxation of the arterioles. Some CNS effects have been reported in patients treated with antihypertensive regimens that included HYLOREL. With a diuretic, HYLOREL is useful in the Step-2 treatment of hypertension.

HYLOREL is a well-tolerated alternative to beta blockers, prazosin, and centrally acting antihypertensives, when a diuretic alone is not enough.

As Effective as Aldomet®*[1]

HYLOREL, in controlled clinical studies, provided blood pressure control comparable to Aldomet, with less drowsiness, depression, and impotence. Patients treated with Aldomet had less diarrhea and fewer orthostatic effects than did those treated with HYLOREL Tablets (guanadrel sulfate).[1]

Orthostatic hypotension, diarrhea, and ejaculation disturbances may occur in patients but seldom have been a cause for discontinuing HYLOREL therapy (see Table 1).

Table 1.
Percent of Patients Discontinuing Therapy

	HYLOREL	Methyldopa	Guanethidine
orthostatic faintness	0.6	0.7	6.0*
syncope	0.4	0.3	2.0
other faintness	1.2	0.0	0.0
increased bowel movements	0.8	0.7	1.4
drowsiness	0.0	1.9*	0.0
fatigue	0.2	2.6*	0.0
ejaculation disturbances	0.4	0.0	0.0
Number of patients analyzed	(481)	(271)	(222)

*Significantly greater than HYLOREL ($p<0.003$).

A Well-tolerated and Useful Choice for Step-2 Treatment of Hypertension

HYLOREL, with a diuretic, is easy to use and economical... for the Step-2 treatment of hypertension.

HYLOREL has not caused a significant change in cardiac output nor adverse effects on liver function.

HYLOREL should not be used in patients with pheochromocytoma nor concurrently with monoamine oxidase inhibitors. HYLOREL should not be given to patients with frank congestive heart failure.

HYLOREL is not contraindicated in patients with ischemic heart disease or peripheral vascular disease.

Two Doses a Day for Most Patients With Hypertension

HYLOREL is prompt acting and rapidly cleared. The dosage can be conveniently titrated. Two doses per day adequately control blood pressure for 24 hours and are associated with minimal morning orthostatic hypotension. Dosage may be adjusted weekly or monthly to fit the patient's needs.

HYLOREL is a Step-2 therapy and should be added to a diuretic regimen for optimal blood pressure control. HYLOREL should be given in divided doses... the usual starting dose is 10 mg per day. The dosage range for most patients is 20 to 70 mg per day.

New for hypertension from Pennwalt

Hylorel® 10 & 25 mg Tablets (GUANADREL SULFATE)

Please refer to the brief summary, including Warnings and Adverse Reactions, on the following page.

Hylorel® 10 & 25 mg Tablets
(GUANADREL SULFATE)

Before prescribing see complete prescribing information; a brief summary follows.

DESCRIPTION: HYLOREL Tablets contain guanadrel sulfate—an antihypertensive agent belonging to the class of adrenergic neuron inhibitors.

CLINICAL PHARMACOLOGY: Guanadrel sulfate is an orally effective antihypertensive agent that lowers both systolic and diastolic arterial blood pressures. Guanadrel sulfate inhibits sympathetic vasoconstriction by inhibiting norepinephrine release from neuronal storage sites and also causes depletion of norepinephrine from nerve endings. This results in relaxation of vascular smooth muscle. No significant change in cardiac output accompanies the blood pressure decline in normal individuals.

INDICATIONS AND USAGE: HYLOREL is indicated for the treatment of hypertension in patients not responding adequately to a thiazide-type diuretic. HYLOREL is Step-2 therapy and should be added to a diuretic regimen for optimum blood pressure control.

CONTRAINDICATIONS: Known or suspected pheochromocytoma; concurrently or within one week of the use of monoamine oxidase inhibitors; patients hypersensitive to the drug; patients with frank congestive heart failure.

WARNINGS: Orthostatic Hypotension and its consequences (dizziness and weakness) are frequent in people treated with HYLOREL. Rarely, fainting upon standing or exercise is seen. Patients with known regional vascular disease (cerebral, coronary) are at particular risk from marked orthostatic hypotension, and HYLOREL should be avoided in them unless drugs with lesser degrees of orthostatic hypotension are ineffective or unacceptable.
Surgery—HYLOREL should be discontinued 48–72 hours before elective surgery to reduce the possibility of vascular collapse during anesthesia. If emergency surgery is required, the anesthesiologist should be made aware that the patient has been taking HYLOREL, and that preanesthetic and anesthetic agents should be administered cautiously in reduced dosage. If vasopressors are needed, they must be used cautiously, as guanadrel can enhance the pressor response to such agents and increase their arrhythmogenicity.
Drug Interactions—Tricyclic antidepressants and indirect-acting sympathomimetics can reverse the effects of neuronal blocking agents. IN VIEW OF THE PRESENCE OF SYMPATHOMIMETIC AMINES IN MANY NON-PRESCRIPTION DRUGS FOR THE TREATMENT OF COLDS, ALLERGY, OR ASTHMA, PATIENTS GIVEN GUANADREL SHOULD BE SPECIFICALLY WARNED NOT TO USE SUCH PREPARATIONS WITHOUT THEIR PHYSICIAN'S ADVICE. Drugs that affect the adrenergic response by the same mechanisms as guanadrel sulfate or by other mechanisms would be expected to potentiate the effects of HYLOREL causing excessive postural hypotension and bradycardia. These include alpha or beta adrenergic blocking agents and reserpine. There is no clinical experience with such combinations.
Asthmatic patients with bronchial asthma: need special attention as their condition may be aggravated by catecholamine depletion and sympathomimetic amines may interfere with the hypotensive effect of guanadrel.

PRECAUTIONS: General—Salt and water retention may occur. In clinical studies, major problems did not arise because of concomitant diuretic use. Patients with heart failure and patients with renal failure have not been studied on HYLOREL. HYLOREL should be used cautiously in patients with a history of peptic ulcer.
Carcinogenesis—No evidence of carcinogenic potential appeared in animal studies.
Mutagenesis—Salmonella testing showed no evidence of activity.
Pregnancy Category B
Impairment of fertility and teratogenic effects—Reproduction studies in rats and rabbits have revealed no evidence of impaired fertility or harm to the fetus due to HYLOREL. There are no adequate and well-controlled studies in pregnant women. HYLOREL should be used in pregnant women only when the potential benefit outweighs the potential risk to mother and infant.
Nursing mothers—It is not known whether or not guanadrel sulfate is excreted in human milk.
Pediatric Use—Safety and effectiveness of guanadrel in children have not been established.

ADVERSE REACTIONS: The adverse reaction data in this section are derived principally from comparative long-term studies with methyldopa and guanethidine. Side effects were assessed through the use of periodic questionnaires, a method that tends to give high adverse reaction rates. Reasons for discontinuation of therapy are shown in the following table.

PERCENT OF PATIENTS WHO DISCONTINUED THERAPY

	Guanadrel	Methyldopa	Guanethidine
Orthostatic faintness	0.6	0.7	6.0
Syncope	0.4	0.3	2.0
Other faintness	1.2	0.0	0.0
Increased bowel movements	0.8	0.7	1.4
Drowsiness	0.0	1.9	0.0
Fatigue	0.2	2.6	0.0
Ejaculation disturbances	0.4	0.0	0.0

The following percentages represent the number of patients who reported an event at least once over the treatment periods (6 months to 3 years). For such long-term studies, these rates for side effects, often found in untreated people as well as in association with adrenergic neuron blocking agents, tend to be high and accumulate with time. The rates for methyldopa and guanethidine should aid in interpretation of this information. It can be seen that serious consequences of the orthostatic effect of guanadrel, such as syncope were very uncommon.

1544 guanadrel, 330 guanethidine and 743 methyldopa patients were evaluated in comparison studies. The observed incidence rates of major drug-related side effects for guanadrel, guanethidine and methyldopa respectively are as follows: Orthostatic faintness: 49%, 48%, 41%; other faintness: 47%, 45%, 46%; increased bowel movements: 31%, 36%, 28%; ejaculation disturbances:18%, 22%, 21%; impotence: 5.1%, 7.2%, 12.2%; syncope: 0.4%, 2%, 0.3%; urine retention: 0.2%, 0%, 0%. Apart from these adverse effects, many others were reported. Relationship to therapy is less clear, although some (such as peripheral edema with all three drugs, depression with methyldopa) are in part drug related. All adverse effects reported in at least 1% of guanadrel patients are listed in the full prescribing information. (This is a brief summary.)

DOSAGE AND ADMINISTRATION: As with other sympathetic suppressant drugs, the dose response to HYLOREL varies widely and must be adjusted for each patient until the therapeutic goal is achieved. With long-term therapy, some tolerance may occur and the dosage may have to be increased.
Because HYLOREL has a substantial orthostatic effect, monitoring both supine and standing pressure is essential, especially while dosage is being adjusted.
HYLOREL should be administered in divided doses. The usual starting dosage for treating hypertension is 10 mg per day, which can be given as 5 mg b.i.d. by breaking the 10 mg tablet. Because the half-life is approximately ten hours, the dosage should be adjusted weekly or monthly until blood pressure is controlled. Most patients will require daily dosage of the range of 20 to 75 mg usually in twice daily doses. For larger doses 3 or 4 times daily dosing may be needed.

COMBINATION THERAPY: HYLOREL has not been studied in combination with antihypertensive drugs other than thiazide diuretics.

HOW SUPPLIED: HYLOREL Tablets (guanadrel sulfate) are available as follows:
10 mg, scored elliptical tablets (light orange)
Bottles of 100 NDC 0018-0787-71
25 mg, scored elliptical tablets (white)
Bottles of 100 NDC 0018-0788-71

Caution: Federal law prohibits dispensing without a prescription.

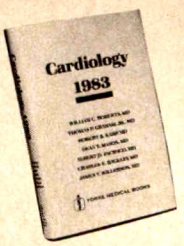
Cardiology 1983

The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery



What is Cardiology 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, **written**, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

CONTENTS

615 Failure of Pretreatment With Propranolol to Reduce the Zone of Myocardial Infarction After 2 Hours of Coronary Occlusion in the Primate Heart

GRAYSON G. GEARY, LYNNE FENTON, GARY CHENG, GREGORY T. SMITH, BENJAMIN SIU, and J. JUDSON McNAMARA

This study assesses the value of pretreatment with propranolol to reduce ultimate myocardial infarct size after acute coronary artery occlusion in the primate heart. An experimental group of 8 baboons was administered a 2-mg/kg loading dose of propranolol intravenously over a 20-minute period before coronary occlusion. This regimen resulted in a significant decrease in heart rate from 104 ± 19 to 73 ± 8 beats/min ($p < 0.001$), peak rate of increase of left ventricular pressure from 2,300 ± 340 to 1,365 ± 307 mm Hg/s ($p < 0.01$), and cardiac output from 1,571 ± 249 to 1,287 ± 360 ml/min ($p < 0.001$). The left anterior descending coronary artery was occluded for a 2-hour period, after which perfusion was restored. A control group of 8 baboons underwent an identical procedure without propranolol therapy. At 24 hours after occlusion, microvascular dyes were injected into the coronary arteries to delineate the anatomic perfusion bed of the previously occluded coronary artery. This allowed histologically assessed infarct size to be expressed as a percentage of the size of the perfusion bed of the occluded artery. The mean percentage of the perfusion bed infarcted in the control group was 54 ± 14% and in the treated group, 55 ± 21% (difference not significant). Hence, despite a significant decrease in heart rate and left ventricular contractility, pretreatment with propranolol did not reduce ultimate infarct size in the primate heart. The failure of propranolol therapy to result in infarct size reduction in the primate heart may be due primarily to the absence of a significant collateral circulation.

621 Dose-Dependent Electrophysiologic Effects of Amiodarone in the Immature Canine Heart

ARTHUR S. PICKOFF, SHARANJEET SINGH, CELIA J. FLINN, EDDA TORRES, ALAN M. EZRIN, and HENRY GELBAND, *With the technical assistance of* JUDITH KASSNER *and* CARLOS A. FLORES

The electrophysiologic effects of intravenous amiodarone in the intact neonatal canine heart are described. Utilizing standard His bundle recording and stimulation techniques, the effects of 2.5 and 10 mg/kg of amiodarone on sinus and atrioventricular (AV) nodal function as well as atrial and ventricular refractory periods were determined and compared with data obtained in a group of adult dogs. In the neonate, amiodarone resulted in prolongation of sinus cycle length, sinus node recovery time and depressed conduction through the AV node. Atrial and ventricular refractory periods were prolonged in a dose-dependent fashion. The neonate had less depression of AV nodal conduction in response to each amiodarone dose than did the adult, and the neonatal atrium appeared to be more sensitive to amiodarone than the adult atrium.

626 Protection of Turkeys Against Furazolidone-Induced Cardiomyopathy

JUDITH K. GWATHMEY and ROBERT L. HAMLIN

Turkey poults fed furazolidone develop dilated cardiomyopathy within 3 weeks. This is manifested by increased heart weight/body weight ratios and by thinning of both the left ventricular free wall and septum. Birds given propranolol, but not digoxin, are protected from developing the cardiomyopathy.

629 Mechanism of Calcification of Porcine Bioprosthetic Aortic Valve Cusps: Role of T-Lymphocytes

ROBERT J. LEVY, FREDERICK J. SCHOEN, and SUSAN L. HOWARD

Calcification of glutaraldehyde-preserved porcine aortic valve bioprostheses limits their success as cardiac valve substitutes. Previous clinical research has suggested that the host's immune response to the porcine xenograft tissue may contribute to the calcific degeneration. To investigate the possible contribution of the immune response, porcine bioprosthetic cusps implanted subcutaneously in congenitally athymic (nude) BALBc mice and normal controls were analyzed biochemically and histologically after retrieval at 21 days. Calcification was comparable in implants retrieved from athymic and normal mice; porcine bioprosthetic cusp calcium accumulation was similar, and the morphology of the calcification was identical. It is concluded that normal T-lymphocyte function is not necessary for calcification in porcine bioprosthetic cusps and that immunologic processes do not significantly contribute to this process.

632 Formation of Cartilage in Bioprosthetic Cardiac Valves Implanted in Sheep: A Morphologic Study

ELOISA ARBUSTINI, MICHAEL JONES, and VICTOR J. FERRANS

Foci of cartilage were found in 12 of 120 bioprostheses implanted in young sheep for 13 to 24 weeks, but in none of 47 bioprostheses implanted for <13 weeks. Cartilage was found more frequently ($p < 0.01$) in bioprostheses

Slow-K®

potassium chloride slow-release tablets 8 mEq (600 mg)

Capsule or tablet slow-release potassium chloride preparations should be reserved for patients who cannot tolerate, refuse to take or have compliance problems with liquid or effervescent potassium preparations, because of reports of intestinal and gastric ulceration and bleeding with slow-release KCl preparations.

A success from the start—and still growing

Before prescribing, please consult Brief Summary of Prescribing Information on next page.

potassium chloride **slow-release tablets**

Brief Summary of Prescribing Information

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.
Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

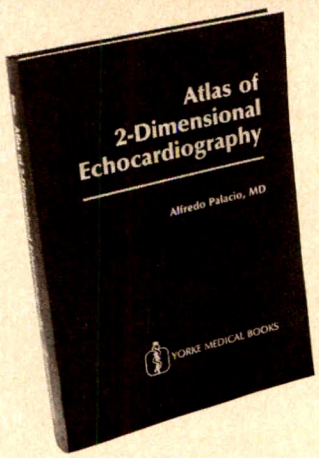
The First Practical Atlas of 2-D Echocardiography Ever Published



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

implanted in the tricuspid position than in those implanted in the mitral position. In porcine aortic bioprostheses, the cartilage was preferentially localized in the region of the muscle shelf; in pericardial bioprostheses, it occurred in the fibrous sheaths covering the cusps. In both instances, the cartilage was found to undergo calcification, considered to be formed by metaplasia of connective tissue cells of host origin.

CORONARY HEART DISEASE

Effect of Interventions in Salvaging Left Ventricular Function in Acute Myocardial Infarction: A Study of Intracoronary Streptokinase

FLORENCE H. SHEEHAN, MD, DETLEF G. MATHEY, MD, JOACHIM SCHOFER, MD, HANS-JOACHIM KREBBER, MD, and HAROLD T. DODGE, MD

The ability of intracoronary streptokinase (STK) infused early in acute myocardial infarction (MI) to salvage left ventricular (LV) function was studied in 52 patients who underwent contrast angiography immediately after STK and 6 ± 7 weeks later. Ten nonrevascularized patients had no lysis or reocclusion. Of 42 patients with thrombolysis, 22 with optimal reperfusion underwent coronary artery bypass grafting (CABG) to prevent rethrombosis (STK + CABG group) and 20 did not (STK group). Motion was measured at 100 chords around the left ventricle and expressed in standard deviations (SD) from the normal mean. Hypokinesia was computed as the mean motion of chords in the infarct artery territory and hyperkinesia on the opposite wall was similarly computed. Hypokinesia improved ≥1 SD/chord in 9 STK + CABG patients (41%), 8 STK patients (30%) (p = not significant versus STK + CABG) and 0 nonrevascularized patients. However, the ejection fraction did not change because it was normal in acute MI despite severe hypokinesia due to hyperkinesia on the opposite wall, and a subsequent decrease in hyperkinesia masked significant improvement in hypokinesia. It is concluded that regional wall motion must be measured to adequately assess the effect of therapeutic interventions on LV function. Early thrombolysis in acute MI results in improved LV function. The main benefit of CABG is to prevent rethrombosis.

(Am J Cardiol 1983;52:431–438)

Much research has been performed in search of therapeutic interventions that decrease the size of a developing myocardial infarction (MI).[1] Because earlier intervention increases the amount of myocardium salvaged,[2,3] reperfusion using a thrombolytic agent may be of benefit in acute MI. Intracoronary streptokinase results in thrombolysis in 64 to 100% of patients.[4–11] However, it is important to determine whether function improves in the MI region. Therefore, the present study assesses the effect of thrombolysis with streptokinase on global and regional left ventricular (LV) function and measures the correlation between global and regional function.

Methods

Streptokinase study: We report 52 patients studied by 2 of us (DGM, JS) at University Hospital Eppendorf, Hamburg, West Germany. All had acute MI diagnosed by a history of typical chest pain of <3 hours' duration and ≥2 mm of ST elevation without abnormal Q waves in the leads of ST elevation. Patients with contraindications to thrombolytic therapy or who required resuscitation and had uncertain neurologic status were excluded.

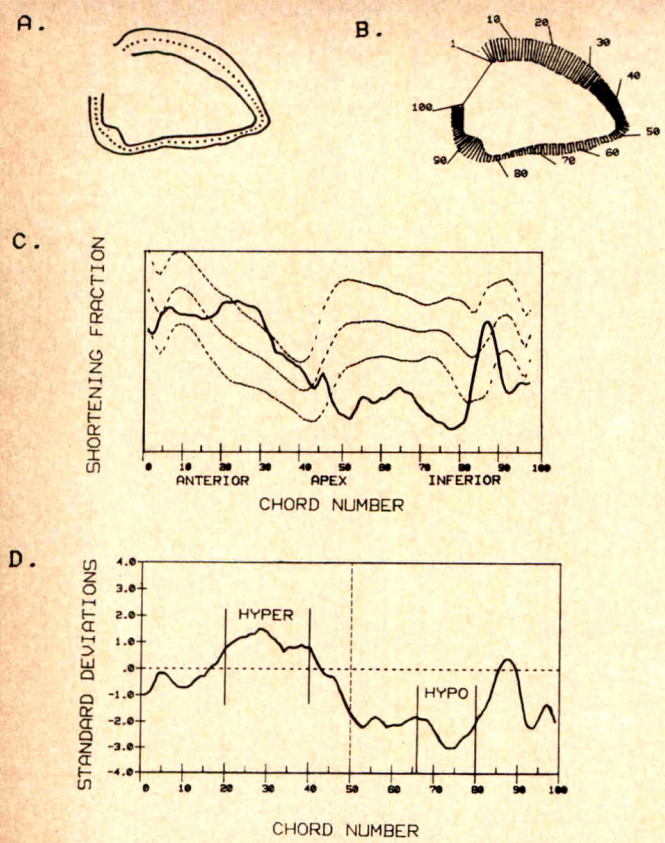

FIGURE 1. Centerline method of analyzing regional left ventricular wall motion. **A,** end-diastolic and end-systolic endocardial contours with centerline. **B,** 100 equidistant chords are constructed perpendicular to the centerline and numbered clockwise from the anterior edge of the aortic valve. The length of each chord is the extent of motion of the corresponding point on the ventricular contour. **C,** wall motion, normalized for heart size (shortening fraction), in a patient (**solid line**) is compared with the motion of the normal group ± 1 standard deviation at each chord. **D,** wall motion of the same patient (**solid line**), plotted in standard deviations from the normal mean (**horizontal dashed line**).

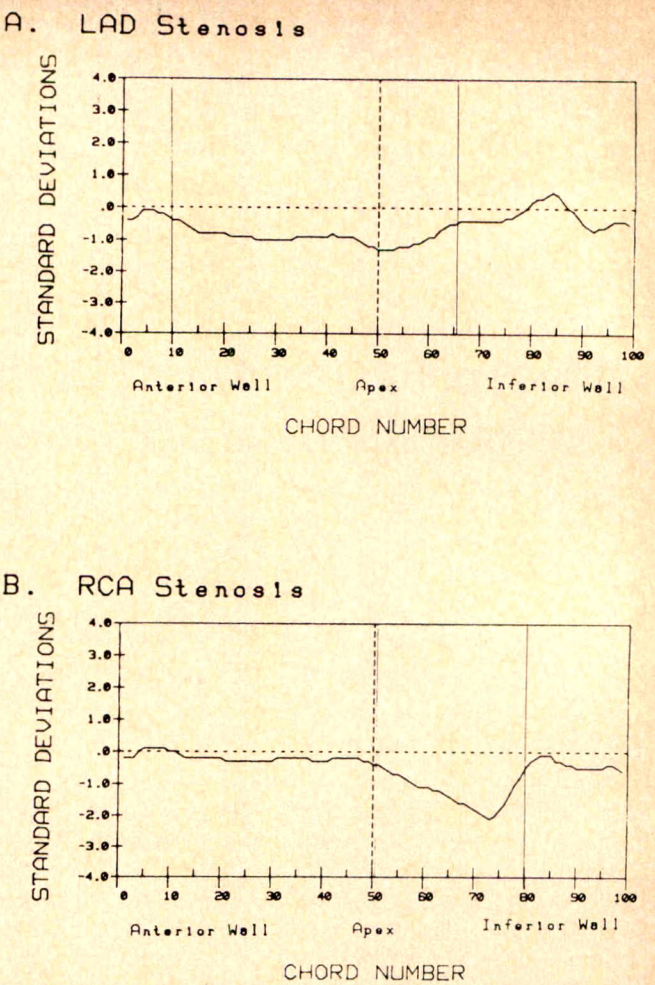

FIGURE 2. Region of the left ventricle affected by stenosis of the left anterior descending (LAD) and right coronary (RCA) arteries. **A,** in patients with isolated stenosis of the LAD, mean wall motion was significantly hypokinetic compared with that in 64 normal patients in the region spanning chords 10 to 66. **B,** in patients with isolated RCA stenosis, mean motion was significantly hypokinetic in chords 51 to 80. SD = standard deviation.

The 52 patients, 44 men and 8 women, represented 30% of all patients admitted with acute MI during the study period and 70% of patients treated with streptokinase. The others had angiograms unsuitable for analysis or refused follow-up study, which was requested in all cases. Mean age was 52 ± 13 years (range 28 to 82). Acute thrombosis involved the left anterior descending coronary artery in 22 patients, the right coronary artery in 23, and the left circumflex artery in 7. Seven patients had previous MI, none <4 months before study and none in the same location as the acute MI.

Coronary angiography was performed by the Judkins technique with hand injection of sodium and meglumine amidotrizoate. Intracoronary nitroglycerin was not given because it was rarely effective.[8] After an intravenous bolus of 10,000 U of heparin, 250,000 U of streptokinase (Streptase, Behring-Werke) were infused at a rate of 4,000 U/min into the ostium of the occluded artery until thrombolysis occurred, then at 2,000 U/min for at least 45 minutes. The usual total dose was 250,000 U (maximum 350,000). Patients received other medication as needed. Left ventriculography was then performed in the right anterior oblique projection using a power injection of 40 ml of contrast through a pigtail catheter. The electrocardiogram score was calculated[12] from standard 12-lead electrocardiograms recorded before streptokinase infusion at a paper speed of 50 mm/s.

In 20 patients, scintigraphy using intracoronary thallium-201 was performed before and after streptokinase therapy in a separate study.[13] Patients who had successful thrombolysis and evidence of myocardial viability by scintigraphy underwent coronary artery bypass surgery (CABG). Patients without scintigrams underwent CABG if no new abnormal Q waves developed after thrombolysis. Thus, patients with optimal reperfusion underwent CABG. Initially, CABG was performed several days after thrombolysis, but in later patients it was performed on the day of thrombolysis because early rethrombosis was occurring. CABG on the day of thrombolysis was not complicated by bleeding. Rethrombosis was diagnosed by repeat coronary angiography in patients who developed chest pain and ST-segment elevation. Angiography was repeated 8 to 230 days after MI (mean 45 ± 49). Cardiac drugs were withheld 24 hours before restudy.

Patients used to validate the method of wall motion analysis: The normal mean and standard deviation (SD) for LV function were defined in a normal reference group of 64 patients studied at the University of Washington or Seattle Veterans Administration Hospitals between 1976 and 1981 who had no coronary artery stenosis ≥50%, history of MI,

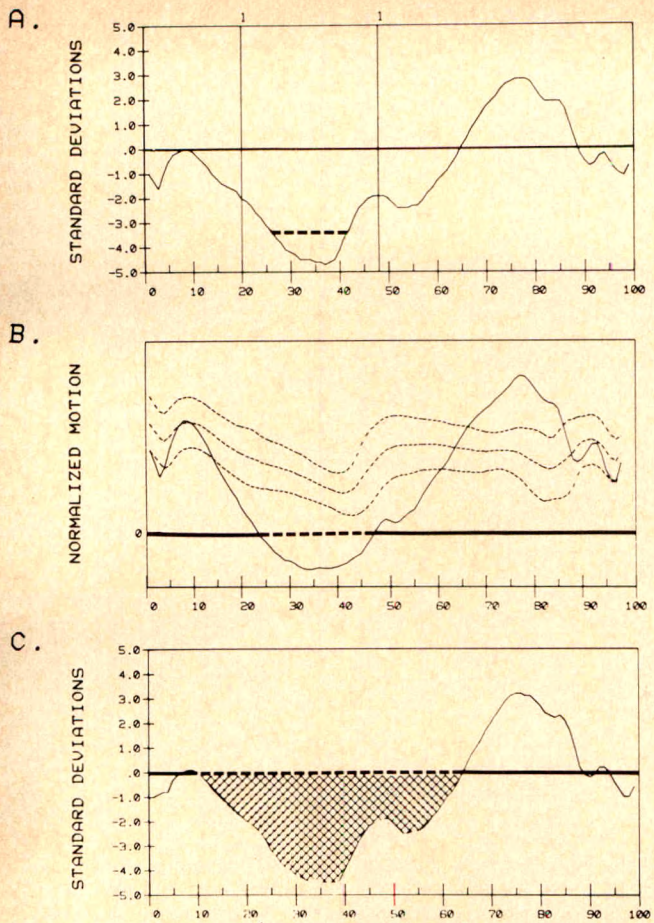

FIGURE 3. Methods of measuring regional wall motion. **A,** patient with isolated occlusion of the left anterior descending artery. The region with most severe hypokinesis is indicated by the vertical lines. The mean chord motion in this region is −3.4 SD, indicated by the **dashed line. B,** in the same patient, the length of the akinetic segment is the number of chords whose motion is 0 or dyskinetic, as indicated by the **dashed portion** of the line at zero motion. **C,** in the same patient, the hypokinetic area (hatched area) is computed by summing the motion of all chords lying within the myocardial infarction artery's territory whose motion is below normal; normal is indicated by the **horizontal line** at 0 standard deviations. The length of the hypokinetic region (**dashed line**) is computed as the number of chords whose motion is less than normal.

sudden death, thoracic surgery or electrocardiographic abnormality other than first-degree atrioventricular block.

The regions of the left ventricle in which motion is affected by stenoses of the coronary arteries were defined in 108 patients (1-vessel disease group) studied at the University of Washington Hospital between 1974 and 1981 who had no history of thoracotomy or valvular or congenital heart disease. Previous MI was present in 32 of 62 patients with stenosis of the left anterior descending coronary artery and in 21 of 46 with right coronary artery stenosis. None had acute MI.

Four methods of wall motion analysis were compared in a separate group of 96 patients (artery group), 49 with chronic stenosis of the left anterior descending or right coronary arteries or both, in whom stenoses could be measured quantitatively, and 47 studied during acute MI.

Analysis of left ventricular volume and regional wall motion: All angiograms were analyzed at the University of Washington. The cinefilms were projected and a normal sinus beat was selected. The end-diastolic endocardial contour was traced from the frame at which the atrial kick was perceived and the end-systolic contour from the frame of minimum volume by visual inspection without operator knowledge of the results of streptokinase therapy. No realignment was performed to correct for cardiac motion within the chest. The contours were entered into a PDP 11/45 computer using an X-Y digitizer. The same observer traced both ventriculograms from each patient. LV volume was calculated by the area-length method.[14] Motion was measured at 100 equidistant chords perpendicular to a center line drawn midway between the end-diastolic contours and numbered clockwise from the anterior aortic valve (Fig. 1).[15] To normalize for heart size, the motion at each chord was divided by the end-diastolic perimeter to yield a dimensionless shortening fraction. Because comparison of different regions requires that motion values be comparable,[16] the normalized motion or shortening fraction (SF_i) of each chord i was converted into units of standard deviations (SD_i) from the normal group mean M_i: $Z_i = (SF_i - M_i)/SD_i$, where Z is expressed in SD (Fig. 1C). If Z is negative, motion is below normal or hypokinetic; a positive Z indicates hyperkinesia.

Wall motion was measured in the region of the LV wall whose function is affected by stenosis of the MI artery (Fig. 2). Artery territories were defined using the 1-vessel disease group. The region of the left ventricle in which mean chord motion in the 62 patients with stenosis of the left anterior descending artery was significantly depressed compared with normal, chords 10 to 66, was defined as that artery's territory. The territory of the right coronary artery was similarly defined as chords 51 to 80 using the mean data of the 46 patients with isolated ≥50% stenosis of the right coronary artery. In patients with stenosis of both arteries, the overlap region was halved and the left anterior descending and right coronary artery territories were assigned chords 10 to 58 and 59 to 80, respectively. In 6 of 7 streptokinase patients with circumflex thrombosis, the hypokinetic region was that of the left anterior descending artery. The seventh patient had a left dominant coronary artery system, and hypokinesia occurred in and was measured in the right coronary artery region.

Hyperkinesia was measured in the chords outside the territory of the MI artery, that is, chords 67 to 80 or 10 to 50 in patients with isolated stenosis of the left anterior descending or right coronary arteries, respectively, and in chords 10 to 58 or 59 to 80, respectively, in patients with stenosis of both arteries. Chords 1 to 10 and 81 to 100 were excluded because of high variability in these regions.[17] Also, chords 81 to 100 overlie the mitral valve.

Within each territory, wall motion was computed as the mean motion of chords lying in the most abnormally contracting region, whose length was restricted to 50% of the territory. This distinguishes patients with coronary artery disease from normal subjects better than motion averaged over longer or shorter regions.[18] Motion in the most hypokinetic region in acute MI was compared with motion in the most hypokinetic region in the second study to avoid regression toward the mean, the bias toward improvement due to the statistical unlikelihood that the same region will be severely abnormal twice.[19]

Study-to-study variability in regional wall motion using the centerline method in patients with stable coronary artery disease is 0.8 ± 0.6 SD/chord in the anterior wall and 0.6 ± 0.4 SD/chord in the inferior wall.[17] Therefore, a change of 1 SD/chord was considered significant.

Comparison of centerline, area and segment length methods: To determine which method of wall motion analysis best detects severe coronary artery stenosis, wall motion measured by the centerline, area and segment length methods was correlated with the severity of coronary artery stenosis assessed quantitatively in artery group patients. Patients with

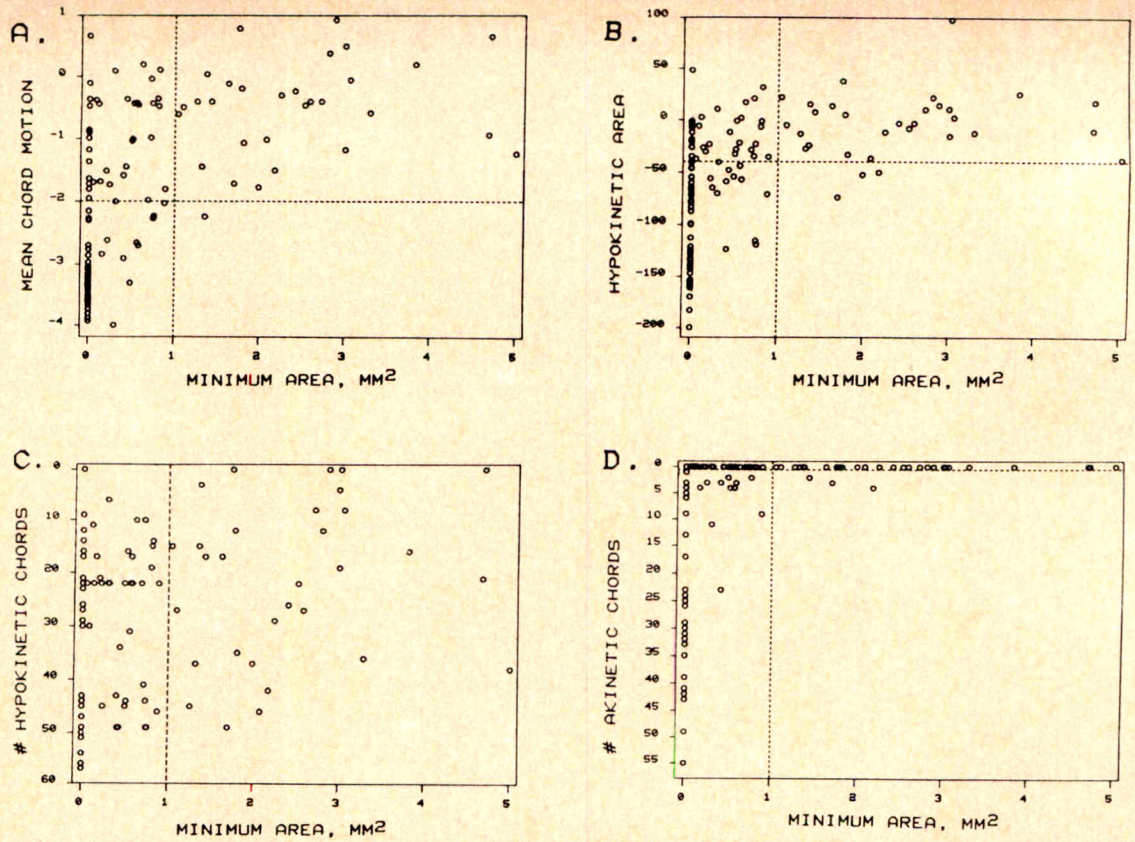

FIGURE 4. Correlation between regional wall motion, measured by 4 methods, and severity of coronary stenosis expressed as the minimum cross-sectional area of the artery lumen at the lesion. **A,** mean chord motion is below −2 standard deviations (SD) in 54 lesions, of which 55 have a minimum area ≤1 mm^2. Thirty-seven lesions have a minimum area ≤1 mm^2 and mean chord motion above −2 SD. **B,** hypokinetic area is below −40 (negative values indicate hypokinesia) in 58 lesions, of which 55 have a minimum area ≤1.0 mm^2. In 36 lesions with a minimum area ≤1 mm^2, the hypokinetic area is above −40 SD chords. **C,** the hypokinetic region has the same length in lesions with minimum area >1.0 and ≤1.0 mm^2. **D,** the akinetic region exceeds 0 chords in length in 49 lesions, of which 46 have a minimum area ≤1.0 mm^2. However, 45 lesions with a minimum area ≤1 mm^2 have no akinesia.

acute MI had total occlusion. In patients with chronic coronary artery stenosis, the minimum cross-sectional area of the stenosis was measured quantitatively using the image reconstruction method.[20] The hypokinetic area was computed by summing the motion of all hypokinetic chords lying within the stenosed artery territory (Fig. 3). The length of the hypokinetic region was computed as the number of chords within the artery territory with less than normal motion. The length of the akinetic segment was measured as the number of chords with motion ≤0.

Statistical analysis was performed using chi-square, 1-way analysis of variance between 3 groups and paired t test.

TABLE I Correlation Between Hypokinesia and Severity of Coronary Stenosis

Method	Stenosis Threshold (mm^2)	Sensitivity (%)	Specificity (%)	Accuracy (%)
Mean chord motion (centerline method)	1.0	59	97	69
	0.5	68	88	76
Hypokinetic area	1.0	60	90	68
	0.5	69	84	75
Akinetic segment length	1.0	49	90	61
	0.5	43	84	68

Results

Comparison of methods of measuring regional left ventricular function: Hypokinesia was correlated with the severity of coronary artery stenosis at 2 thresholds: minimum area ≤0.5 mm^2 and ≤1.0 mm^2 (Fig. 4). These limits approximate the mean plus 2 SD for stenosis in patients with unstable angina and MI.[21] Mean chord motion computed by the centerline method was defined as hypokinetic if depressed more than 2 SD below normal. Chi-square analysis was used to determine the threshold yielding the most significant correlation between hypokinesia and severity of coronary artery stenosis for the other 3 methods. The thresholds were hypokinetic area exceeding −40 SD/chords (Fig. 4B), and akinetic segment length >0 (Fig. 4D). Hypokinetic segment length (Fig. 4C) varied widely and did not correlate with the severity of stenosis. At these thresholds, the sensitivity, specificity, and accuracy of mean chord motion calculated using the centerline method were greater than those of the hypokinetic area and akinetic segment length (Table I). The range for mean chord motion measured by the centerline method, but not for the hypokinetic area, is similar in stenoses of the left anterior descending (0 to −3.2 SD/chord) and right coronary arteries (0 to −4.0 SD/chord) and allows

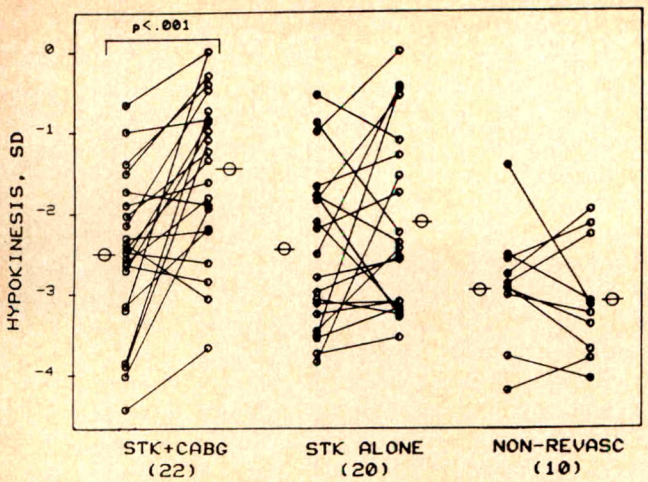

FIGURE 5. Change in hypokinesia in the region of acute ischemia in acute and follow-up studies in each patient group. STK + CABG = patients who had thrombolysis, optimal reperfusion and coronary artery bypass surgery; STK = patients with thrombolysis but who developed Q waves or had large residual perfusion defects on thallium scan; Non-Revasc = patients without thrombolysis or with rethrombosis; SD = standard deviation. The number of patients in each treatment group in shown in parentheses.

them to be analyzed together. Therefore, the centerline method was used to analyze the streptokinase study.

Streptokinase study: The streptokinase (STK) patients were divided into 3 groups. The STK + CABG group consisted of 22 patients who underwent CABG regardless of graft patency at follow-up study. In 10, serial scintigraphy had revealed little or no residual defect. Patients without thrombolysis (n = 5) or with rethrombosis (n = 5) comprised the nonrevascularized group. Those in the STK group (n = 20) had thrombolysis but no CABG because (1) thallium scintigraphy failed to demonstrate myocardial variability (n = 6) or (2) Q waves appeared after reperfusion.

Hypokinesia in the acute study in the 3 groups averaged −2.6 ± 0.9 SD/chord, but mean ejection fraction (EF) was near normal, 55 ± 14% (Fig. 5). In STK + CABG patients, hypokinesia improved ($p < 0.001$) from −2.5 ± 1.0 SD/chord to −1.5 ± 1.0 SD/chord in STK + CABG patients, from −2.5 ± 1.0 to −2.1 ± 1.1 SD/chord (p = not significant [NS]) in STK patients, and became worse from −2.9 ± 0.7 to −3.1 ± 0.7 SD/chord (p = NS; $p < 0.005$ from STK + CABG) in nonrevascularized patients. Only patients with reperfusion had ≥1 SD improvement in hypokinesia (Fig. 6). The improvement in STK + CABG patients was not due to CABG because hypokinesia improved slightly more in patients operated on >24 hours after the onset of chest pain than within 24 hours (1.3 ± 1.2 versus 0.8 ± 1.0 SD/chord, p = NS). In patients whose hypokinesia became worse, the decrease in motion was less severe in the STK + CABG group than in the STK group (−0.3 ± 0.3 versus −0.9 ± 0.5 SD/chord, respectively, $p < 0.05$).

The improved function in the MI region in STK + CABG patients was not reflected by the global EF, which increased only slightly (from 57 ± 15 to 59 ± 13%, p = NS) (Fig. 7). The EF decreased in STK patients from 54 ± 15 to 50 ± 15% (p = NS) and in nonrevascularized patients from 53 ± 4 to 46 ± 6% ($p < 0.005$). The improvement in EF (1.4 ± 9.3%) in STK + CABG patients differed significantly from the decrease in EF in the nonrevascularized group (−6 ± 5%, $p < 0.05$), but not from the decrease in STK patients (−4 ± 9%, p = NS). The EF increased by ≥5% in a similar proportion of STK = CABG patients (7 of 22, 32%) and STK patients (5 of 20, 25%) but in none of the 10 nonrevascularized patients (p = NS).

To determine why the EF failed to reflect the improved wall motion in the MI region, hyperkinesia on the wall opposite the acute MI was measured. Hyperkinesia averaged 1.1 ± 1.1 SD/chord, significantly higher ($p < 0.005$) than the 0.4 ± 0.6 SD/chord measured in patients with chronic coronary artery disease selected from University of Washington files and matched with the streptokinase patients by sex, location of coronary artery stenoses, and previous MI. Hyperkinesia decreased in all 3 groups, from 1.1 ± 1.0 to 0.8 ± 0.9 SD/chord in STK + CABG patients, from 1.2 ± 1.2 to 0.3 ± 0.6 SD/chord ($p < 0.001$) in STK patients, and from 0.9 ± 0.8 to 0.4 ± 5 SD/chord in nonrevascularized patients (Fig. 8). Hyperkinesia decreased by ≥1 SD/chord in a similar proportion of patients in all 3 groups (5 of 22, 7 of 20, and 1 of 10, respectively, in STK + CABG, STK and nonrevascularized). Hyperkinesia in acute MI was similar in patients who did and in those who did not require catecholamine support (1.1 ± 1.2 SD/chord, n = 8, versus 1.0 ± 1.0 SD/chord, n = 44). The decrease in hyperkinesia between studies was also similar in these 2 subgroups (−0.8 ± 1.4 versus −0.5 ± 0.9 SD/chord, respectively).

Although mean hyperkinesia decreased in the group as a whole, hyperkinesia increased in 8 patients, by ≥1 SD in 4 patients. The increase in hyperkinesia was not

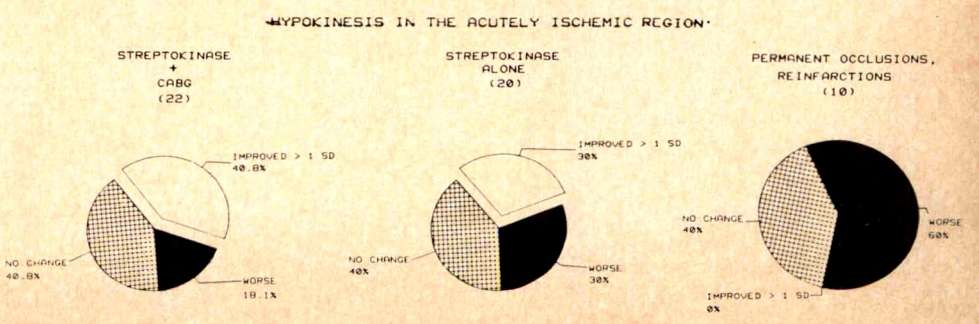

FIGURE 6. Hypokinesia in the acutely ischemic region—the proportion of patients in each group in whom hypokinesia improved by ≥1 standard deviation (SD) (Improved, **white area**), did not change or improved by <1 SD (No Change, **hatched area**), or worsened (Worse, **black area**) in the interim between acute and follow-up studies. Abbreviations as in Figure 5.

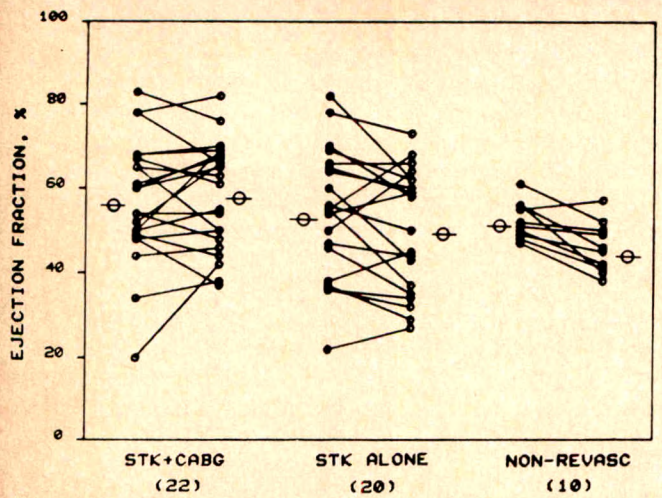

FIGURE 7. Change in ejection fraction in acute and follow-up studies in each patient group. Abbreviations as in Figure 5.

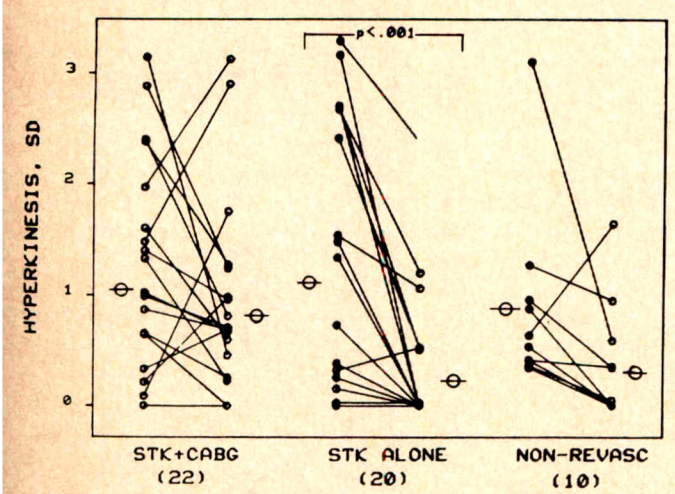

FIGURE 8. Change in hyperkinesia on the wall opposite the acutely ischemic region in acute and follow-up studies in each patient group. Abbreviations as in Figure 5.

significantly related to the initial severity of or change in hypokinesia, patient age, duration of occlusion, MI artery or treatment group, although it was slightly more common in patients with 1-vessel coronary disease, and the percent of stenosis assessed visually in the artery opposite the MI was lower (18 ± 35) in patients with ≥1 SD increase in hyperkinesia than in those without an increase (34 ± 41%, p = NS) (stenosis was coded as 0% if successfully bypassed).

The present study was not a randomized trial of streptokinase. However, the 3 patient groups were similar in severity of disease (Table II).

The time from onset of chest pain to thrombolysis (or to cessation of streptokinase in nonreperfused patients) did not correlate with the change in hypokinesia or EF, perhaps because it was short (mean 3.0 ± 1.0 hours). Indeed, no factor could be identified that predicted success in achieving thrombolysis.

Discussion

Many methods have been developed to measure regional LV function from contrast angiograms.[16,22–24] The centerline method was designed to avoid some inadequacies of the older methods. First, the centerline method uses no coordinate system and does not assume that the LV walls contract toward a central long axis or point. Second, motion is measured on a continuous scale. In contrast, measurement of the percent of the LV circumference[24] that is akinetic or below an arbitrary threshold such as −2 SD limits interpretation of the data, decreases accuracy because variability in the measurement could push a value across the threshold in the absence of real change or hide a significant change because it fails to cross the threshold,[19] and implies without justification that a localized but severe motion abnormality is more significant than an extensive abnormality of only moderate (below threshold) severity. Third, variability is reduced in the centerline method because identification of the apex as a landmark is not required. This may cause inaccuracy in methods based

TABLE II Streptokinase Patient Groups

	STK + CABG	STK	Nonrevascularized
Patient age (yr)	52 ± 12*	54 ± 16	50 ± 11
Males/females	20/2	17/3	8/2
Infarct artery

Q ≥0.03 second in lead of ST elevation	8	9	5
LV function in acute study			
Ejection fraction (%)	57 ± 15	54 ± 15	53 ± 4
Hypokinesia, SD/chord	−2.5 ± 1.0	−2.5 ± 1.0	−2.9 ± 0.7
Hyperkinesia, SD/chord	1.1 ± 1.0	1.2 ± 1.2	0.9 ± 0.8

* Mean ± standard deviation.
† From onset of chest pain to reperfusion or to cessation of streptokinase infusion in nonrevascularized patients.
LV = left ventricular; STK = streptokinase; STK + CABG = streptokinase + coronary bypass graft surgery; nonrevascularized = patients without thrombolysis or with rethrombosis.

on rectangular or radial coordinate systems because the apex is sometimes poorly visualized.[17] Variability is further minimized in the centerline method because motion is averaged over the region of interest.[17] Fourth, the region of interest can be defined precisely. As a result, the discriminant power of the centerline method equals or exceeds that of other methods, as shown in the present study and in a previous report.[25]

In analyzing serial studies, the most hypokinetic regions in the 2 studies were compared. The chord number of the most hypokinetic region varied by <5% of the endocardial contour length. Actually, because the left ventricle lacks anatomic landmarks, it is impossible to identify regions and assign them the same chord number twice by any method of wall motion analysis. A change in ventricular shape, as with dilatation or regional changes in contractility, would cause renumbering because of relative change in centerline length, shifting origin in methods based on center of mass, or shifting apex in coordinate system methods. For these reasons, a region may have a different chord number when restudied. Conversely, comparison of the most hypokinetic region in the acute study with the region of the same chord number in the second study does not guarantee that the same point on the left ventricle was studied, regardless of the method of analysis used, and risks statistical bias toward improvement due to regression toward the mean.[19]

In the present study the EF underestimated both the severity of hypokinesia in acute MI and the improvement in patients with optimal reperfusion (STK + CABG group) because hyperkinesia decreased on the wall opposite the MI. The EF decreased in the STK group despite a small improvement in hypokinesia due to a significant decrease in hyperkinesia. Thus, full assessment of LV function requires analysis of both hypokinesia in the infarct region and hyperkinesia in the opposite wall.

Improvement in regional hypokinesia after successful thrombolysis by streptokinase has been reported.[4–6,10] Our results indicate that streptokinase improves wall motion in the infarct region in some patients, but other factors are also involved. One factor is prevention of rethrombosis, our motive for recommending CABG. None of the patients with rethrombosis had ≥1 SD/chord improvement in hypokinesia. Although mean motion improved only in the STK + CABG group, it is unlikely that CABG effected that improvement because: (1) Patients recommended for CABG had better reperfusion that non-CABG patients who had residual perfusion defects on the thallium scan or developed new Q waves on the electrocardiogram. (2) To salvage myocardium, revascularization must be performed early.[2,3] (In this study almost half the patients had CABG >24 hours later, yet improved more than those operated on the day of MI.) (3) The proportion of patients who improved by at least 1 SD/chord was similar in reperfused patients who did or did not undergo CABG. Thus, the main benefit of CABG may be to prevent rethrombosis.

A second factor determining improvement after reperfusion may be the severity of residual stenosis in the MI artery. If flow-restricting, ischemia may continue because of selective underperfusion of the subendocardium.[26]

Third, angiographic reperfusion of the epicardial coronary arteries is not equivalent to microvascular reperfusion; persistence of a scintigraphic perfusion defect may be analogous to the no-reflow phenomenon[27] and may indicate that necrosis has begun. Finally, collateral circulation may prolong the period of ischemia tolerated before necrosis begins.[6] Further work is needed to clarify these points and, more importantly, to better define the population of patients most likely to benefit from thrombolytic therapy.

Hyperkinesia in the wall opposite the MI has previously been reported[28] and attributed to a Frank-Starling mechanism or to catecholamine release. Hyperkinesia may also be due to unloading of the normal wall due to the decreased contractile force exerted by the MI region. Failure by some[4,29] to document hyperkinesia is probably due to the different methods of wall motion analysis used, because the centerline method is more sensitive in detecting hyperkinesia than either radial or rectangular coordinate methods.[25]

The increase in hyperkinesia in some patients may be due to the development of chronic compensatory hyperkinesia, which has been described months after an MI and is associated with better global function.[30] Biochemical studies in animals suggest that hyperkinesia develops because of hypertrophy.[29] The factors that determine whether a patient will develop chronic hyperkinesia are unclear. Chronic hyperkinesia tended to occur more frequently in patients without severe stenosis of the artery opposite the site of infarct, but was unrelated to the severity of hypokinesia in the infarct region.

Hemodynamic Effects of Intravenous Prostacyclin in Stable Angina Pectoris

BRIAN G. FIRTH, MD, DPhil, MICHAEL D. WINNIFORD, MD,
WILLIAM B. CAMPBELL, PhD, and L. DAVID HILLIS, MD

Prostacyclin (PGI_2) is a naturally occurring vasodilator and inhibitor of platelet aggregation that produces vasodilatation of the systemic, pulmonary and coronary vascular beds in animal models. Because the endogenous production of PGI_2 is reduced in those with coronary arterial disease (CAD), it may have a therapeutic role in patients with ischemic heart disease. To assess its safety and efficacy in this clinical setting, 17 patients with stable angina and CAD received an incremental intravenous infusion of either PGI_2 ($n = 10$) to a maximum dose of 10 ng/kg/min (average 9.8 ± 0.8 [mean ± standard deviation]), or diluent buffer solution (placebo) ($n = 7$). All patients who received PGI_2 became flushed, but experienced no other adverse effects. PGI_2 caused an increase in heart rate (66 ± 11 to 80 ± 11 beats/min, $p < 0.001$) and cardiac index (2.88 ± 0.65 to 3.97 ± 1.17 liters/min/m^2, $p < 0.001$) and a decrease in mean femoral arterial pressure (96 ± 18 to 86 ± 11 mm Hg, $p < 0.001$), but no change in mean pulmonary arterial or capillary wedge pressure. Total systemic and pulmonary vascular resistance decreased significantly ($p < 0.001$). In response to PGI_2, mean coronary sinus blood flow did not change significantly (100 ± 40 to 121 ± 52 ml/min), but coronary vascular resistance decreased (1.07 ± 0.40 to 0.83 ± 0.36 U, $p < 0.001$). No variable was altered by placebo infusion. PGI_2 caused a marked increase in 6-keto $PGF_{1\alpha}$ (the stable metabolite of PGI_2) concentrations in both arterial (42 ± 29 to 567 ± 216 pg/ml, $p < 0.001$) and venous (46 ± 31 to 604 ± 229 pg/ml, $p < 0.001$) blood but no demonstrable change in plasma renin activity. Thus, intravenous PGI_2 to a dosage of 10 ng/kg/min is a safe and effective systemic, pulmonary and coronary arterial vasodilator in patients with CAD and stable angina pectoris.

(Am J Cardiol 1983;52:439–443)

Prostacyclin (PGI_2), a naturally occurring vasodilator and inhibitor of platelet aggregation, is synthesized from arachidonic acid by vascular endothelial cells.[1–7] When administered intravenously or intraarterially, it causes systemic and pulmonary vasodilatation.[8] Recent studies demonstrate that intravenous PGI_2 infusion may be efficacious in several conditions, including congestive heart failure[9] and pulmonary hypertension.[10] In systemic atherosclerosis, endogenous PGI_2 production is reduced,[11,12] and its intravenous infusion may provide symptomatic improvement in patients with advanced peripheral vascular disease and rest pain.[13] Similarly, endogenous PGI_2 production is diminished in patients with coronary artery disease (CAD).[14] This observation, in conjunction with the finding in animals that this substance causes coronary arterial vasodilation,[5,15,16] suggests a therapeutic role for PGI_2 in patients with various CAD syndromes such as unstable angina and acute myocardial infarction. However, before it is widely used in such patients, its effects on systemic, pulmonary and coronary hemodynamics require elucidation. Therefore, the present study was performed to assess the influence of an incremental-dose intravenous PGI_2 infusion on cardiac output, coronary blood flow, intracardiac filling pressures and vascular resistance in patients with CAD and stable angina pectoris.

Methods

Patients: The study was performed in 17 patients (10 men, 7 women, mean age 51 years) with angiographic evidence of CAD (≥70% luminal diameter narrowing of ≥1 major coronary arteries) and stable angina pectoris. Informed consent was obtained from all patients. Patients with recent myocardial infarction or a bleeding tendency were not eligible. All data were collected before the introduction of radiographic contrast material and the systemic administration of heparin. Nitroglycerin was not administered during the catheterization procedure. Each patient was randomly assigned to receive 1 of 2 agents: PGI_2 (n = 10) or glycine buffer solution (placebo) (n = 7). The clinical characteristics of the patients assigned to PGI_2 were similar to those of the patients who received placebo (Table I).

Study protocol: In each patient, a thermodilution catheter (model CCS-7N-90B, Wilton Webster Laboratories) was advanced to the coronary sinus from the right basilic vein and its position was confirmed fluoroscopically and oximetrically. The flow-measuring thermistor was positioned just inside the ostium of the coronary sinus on the basis of the fluoroscopic assessment of the position of the ostium. Once the thermistor had been positioned satisfactorily and a test measurement of coronary sinus flow made to confirm that the thermistor was indeed in the coronary sinus and not in the right atrium, the catheter was not moved until all measurements had been completed. A No. 8 Fr sheath fitted with a hemostatic valve and side port extension (Cordis Corporation) was introduced percutaneously into the femoral artery and vein, after which a balloon-tipped thermodilution catheter was advanced through the femoral vein to the pulmonary artery. Before infusion, femoral arterial, pulmonary arterial and pulmonary capillary wedge pressure, as well as cardiac output and coronary sinus blood flow by thermodilution, were measured in triplicate. In addition, blood samples were obtained from the femoral venous and arterial sheaths for measurement of 6-keto $PGF_{1\alpha}$ (the stable metabolite of PGI_2) and plasma renin activity.

PGI_2 infusion: In 10 patients (7 men, 3 women, mean age 52 years), PGI_2 (provided by the Upjohn Company) was infused intravenously after completion of the baseline measurements. Two of these 10 patients had significant 1-vessel, three 2-vessel, and five 3-vessel CAD. Medical therapy, which included beta-adrenergic blocking agents in 9, long-acting nitrate preparations in 6 and calcium antagonists in 6 (Table I), was withheld for 8 hours before the study. The PGI_2 was prepared as a sterile power dissolved in glycine buffer (pH 10.5) and diluted to a concentration of 50 μg/ml. Subsequently, an aliquot of this concentrated solution was added to 250 ml of saline solution, yielding a final concentration of 342 ng/ml. This solution was kept at 2 to 8°C and administered within 2 hours of its preparation. PGI_2 was infused by a microinfusion pump (Harvard Apparatus) through a peripheral venous cannula at incremental doses of 2.5, 5.0, 7.5 and 10 ng/kg/min, each for 15 minutes. At the peak infusion rate, femoral arterial, pulmonary arterial and pulmonary capillary wedge pressure, as well as thermodilution-determined cardiac output and coronary sinus blood flow in triplicate, were again measured, and femoral arterial and venous blood samples were obtained for quantitation of 6-keto $PGF_{1\alpha}$ and plasma renin activity. In 1 patient, the infusion was discontinued after 7.5 ng/kg/min because of atypical chest pain, whereas the remaining 9 patients tolerated 10 ng/kg/min without developing angina. All became flushed during PGI_2 infusion, but no other adverse effects were evident. After the peak infusion rate, the PGI_2 infusion was down-titrated over 15 to 20 minutes.

Glycine buffer (placebo) infusion: In 7 patients (3 men, 4 ministered after baseline measurements. Three had significant 1-vessel, 2 had 2-vessel and 2 had 3-vessel CAD. Of these 7 patients, 2 were taking beta-adrenergic blocking drugs, 6 long-acting nitrates, and 3 calcium antagonists until 8 hours before the study. Glycine buffer (without PGI_2 powder) was added to saline solution, after which its incremental infusion was performed in a manner identical to that just described. No side effects were evident during or after glycine buffer infusion.

Chemical analyses: Because of the short half-life of PGI_2, the plasma concentration of its stable metabolite 6-keto $PGF_{1\alpha}$ was measured.[6] The blood samples for prostaglandin analysis were drawn simultaneously into heparinized plastic syringes and transferred quickly to iced 12-ml tubes containing indomethacin (10 μg) and heparin (1,000 U). They were centrifuged at 2,000 × *g* for 15 minutes at 4°C, and the supernatants were separated and stored at −45°C for subsequent analysis. Plasma 6-keto $PGF_{1\alpha}$ concentrations were measured by the radioimmunoassay method of Dray et al[17] as modified by Campbell et al,[18] as described previously from our laboratory.[19,20] Plasma renin activity was measured by the method of Poulsen and Jorgensen.[21]

Statistical analyses: All values are expressed as mean ± standard deviation. The 2 groups were compared at baseline using Hotelling's T-square analysis.[22] A repeated measures analysis of variance with 1 grouping factor was performed to test for differences between groups and from baseline to peak infusion.[23] When significant interaction was found, Newman-Keul comparisons were made. Otherwise, Duncan's multiple-range test was used to locate significant differences.[23] Linear regression analyses were used to compare both absolute and percent changes in coronary blood flow and coronary vascular resistance from baseline to peak infusion with the changes in mean femoral arterial pressure, diastolic femoral arterial pressure, heart rate–systolic arterial pressure double product, cardiac index and total systemic vascular resistance.[23] A p value <0.05 using a 2-tailed *t* test was considered significant.

Results

Systemic, pulmonary, and coronary hemodynamic alterations: At baseline, the PGI_2 and placebo-treated groups were similar in all respects (Table I). PGI_2 caused an increase in heart rate (from 66 ± 11 to 80 ± 11 beats/min, $p < 0.001$) and cardiac index (from 2.88 ± 0.65 to 3.97 ± 1.17 liters/min/m^2, $p < 0.001$), a decrease in mean femoral arterial pressure (from 96 ± 18 to 86 ± 11 mm Hg, $p < 0.01$) and diastolic femoral arterial pressure (from 69 ± 11 to 61 ± 8, $p < 0.01$), but no change in mean pulmonary arterial pressure (18 ± 4 mm Hg before and after) or capillary wedge pressure (from 10 ± 3 to 11 ± 4 mm Hg, difference not significant [NS]). Double product showed no consistent response and the mean value did not change significantly with PGI_2 (from 8.9 ± 2.2 to 9.7 ± 1.8 × 10^3 U). Both total systemic vascular resistance (from 1,559 ± 550 to 1,040 ± 375 dynes s cm^{-5}, $p < 0.001$) and total pulmonary vascular resistance (from 298 ± 105 to 214 ± 78 dynes s cm^{-5}, $p < 0.001$) decreased. The infusion of placebo produced no significant change in these variables.

PGI_2 caused an increase in coronary sinus blood flow in 7 patients, no change in 1 and a decrease in 2. The mean coronary sinus blood flow did not change significantly (from 100 ± 40 to 121 ± 52 ml/min, NS). Coronary vascular resistance decreased in 9 patients and increased minimally in 1, so that the average coronary

± 0.36 U ($p < 0.001$). In the 7 patients receiving placebo, coronary blood flow increased in 3, decreased in 3 and changed minimally in 1, whereas coronary vascular resistance decreased in 3, increased in 2, and changed minimally in 2. Glycine buffer produced no significant change in either of these variables.

There was a weak correlation between the absolute change in coronary blood flow in response to PGI_2 and the change in both cardiac index ($r = 0.60$, $p = 0.067$) and total systemic vascular resistance ($r = -0.62$, $p = 0.054$), but these relations were not statistically significant. The correlations between the absolute change in coronary blood flow and mean femoral arterial pressure, diastolic femoral arterial pressure and double product did not approach statistical significance. Similarly, the relation between the percentage change in coronary blood flow and the percentage change in any of the aforementioned variables did not approach statistical significance. Finally, there was no correlation between the absolute change or the percentage change in coronary vascular resistance and the absolute or percentage change in the other variables.

Neither double product nor coronary blood flow changed consistently in response to PGI_2, and the correlation between both the absolute and percentage changes in coronary blood flow and double product was not significant. Nevertheless, these 2 variables consistently changed in the same direction.

Serologic alterations: PGI_2 produced a marked increase in 6-keto $PGF_{1\alpha}$ levels in both femoral arterial blood (from 42 ± 29 to 567 ± 216 pg/ml, $p < 0.001$) and venous blood (from 46 ± 31 to 604 ± 229 pg/ml, $p < 0.001$). In contrast, the levels of 6-keto $PGF_{1\alpha}$ in femoral arterial blood (from 14 ± 18 to 13 ± 21 pg/ml, NS) and venous blood (from 14 ± 18 to 17 ± 20 pg/ml, NS) were unaltered in the placebo-treated group (Fig. 1). Conversely, PGI_2 caused no significant change in plasma renin activity (from 0.67 ± 0.57 to 2.07 ± 2.60 ng A_1/ml/h, NS).

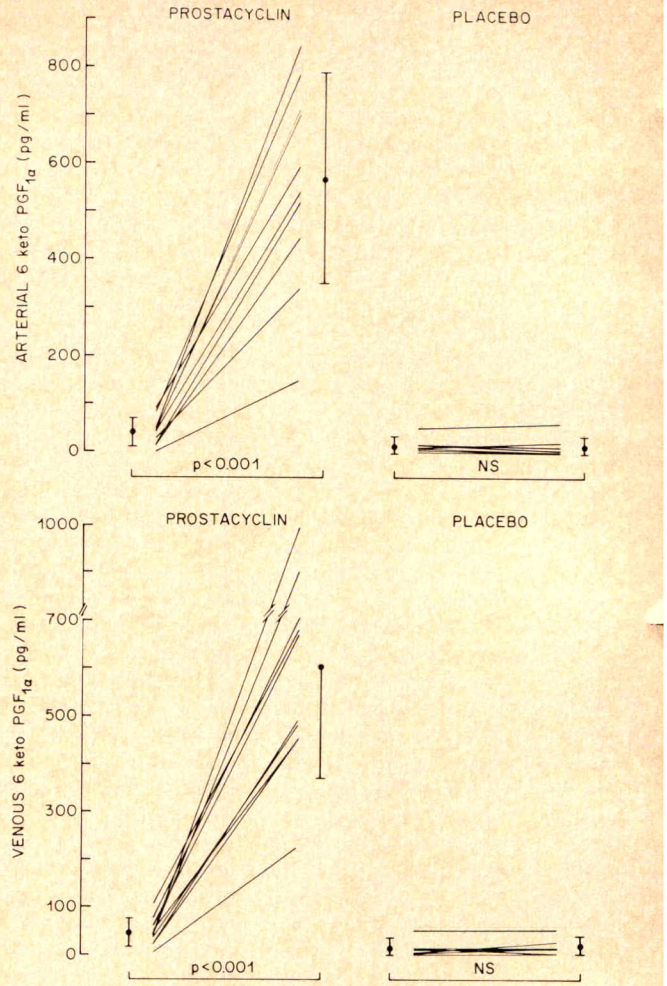

FIGURE 1. Effects of prostacyclin and placebo, respectively, on arterial (**above**) and venous (**below**) 6-keto $PGF_{1\alpha}$ concentrations. Each line represents the data from a single patient, and the means ± 1 standard deviation are shown. Prostacyclin caused a marked increase in both arterial and venous 6-keto $PGF_{1\alpha}$ concentrations.

Discussion

Over the past few years, the infusion of PGI_2 has proved beneficial in patients with congestive heart failure,[9] pulmonary hypertension[10] and arteriosclerotic peripheral vascular disease.[13] Preliminary observations suggest that it may exert a salutary effect in those with angina pectoris at rest.[24] The present study was performed to explore its safety and hemodynamic effects in patients with arteriosclerotic CAD.

Systemic and pulmonary hemodynamic alterations induced by PGI_2: In this study, the intravenous infusion of PGI_2 in patients with CAD and stable angina pectoris produced an increase in heart rate and cardiac index, a decrease in mean and diastolic systemic arterial pressure, and a decrease in total systemic and pulmonary vascular resistance, findings similar to those reported previously in normal persons,[25,26] those with CAD,[27] and those with congestive heart failure.[9] At the same time, PGI_2 induced no consistent change in the double product (an index of myocardial oxygen demand), or pulmonary arterial or pulmonary capillary wedge pressure. Other investigators reported similar findings when the pulmonary capillary wedge and pulmonary arterial pressures were not elevated.[25–27] Thus, the influence of PGI_2 on cardiac output, heart rate, intracardiac filling pressure and vascular resistance in the present study is similar to that reported previously.

Coronary hemodynamic changes caused by PGI_2: In this study, intravenous PGI_2 produced a decrease in coronary vascular resistance ($p < 0.001$) but no significant change in coronary blood flow. In canine models of myocardial ischemia, others[15,16] have noted a dose-dependent decrease in coronary vascular resistance but no change in coronary blood flow with intravenous PGI_2, whereas intracoronary PGI_2 has increased coronary blood flow. Our findings differ from those of Bergman et al,[27] who showed a significant PGI_2-induced increase in coronary blood flow and a decrease in coronary vascular resistance in patients with stable angina. We withheld antianginal medications (including beta-adrenergic blocking agents) for only 8 hours, whereas Bergman et al[27] withheld these agents for 48 hours; therefore, persistent beta-adrenergic blockade in our

patients could explain the difference in coronary blood flow response in our study compared with theirs. In our study, coronary blood flow increased in most patients despite a marked decrease in mean and diastolic systemic arterial pressures, an event that cannot occur in the absence of coronary vasodilatation. In addition, alterations in myocardial oxygen demand (as reflected by double product[28]) probably exerted an effect on coronary blood flow independent of that produced by PGI_2, because PGI_2 caused directionally similar alterations in coronary blood flow and double product. In short, both our study and that of Bergman et al[27] suggest that intravenous PGI_2 produces coronary vasodilatation in patients with CAD.

Although PGI_2 produced a decrease in coronary vascular resistance in patients with CAD, this change may not improve the blood supply to marginally perfused regions of myocardium. In a canine model of myocardial ischemia, Ribeiro et al[29] demonstrated no increase in total flow to ischemic myocardium and no change in the endocardial/epicardial flow ratio in response to PGI_2. Nevertheless, according to these and other investigators,[30,31] PGI_2 diminished the extent of myocardial ischemic injury, possibly through a reduction in the determinants of myocardial oxygen consumption. In patients with CAD and stable angina, 2 recent studies[24,27] reached disparate conclusions about the efficacy of intravenous PGI_2 in preventing pacing-induced ischemia: Bergman et al[27] noted a PGI_2-induced increase in anginal threshold with pacing, whereas Szczeklik et al[24] observed no change. Finally, Szczeklik et al[24] reported a consistent symptomatic improvement with intravenous PGI_2 in patients with recurrent episodes of angina at rest, but Chierchia et al[32] observed symptomatic improvement in only 1 of 9 patients with this clinical syndrome.

Serologic alterations produced by PGI_2: PGI_2 caused a marked increase in plasma 6-keto $PGF_{1\alpha}$ in both arterial and venous blood in comparison with placebo (Fig. 1), an expected finding because 6-keto $PGF_{1\alpha}$ is the major metabolite of PGI_2.[6] The similar levels of 6-keto $PGF_{1\alpha}$ in venous and arterial blood after PGI_2 imply that it (unlike PGE_2) is not degraded by passage through the lungs, an observation noted by others.[3,4] In contradistinction to its effects on plasma 6-keto $PGF_{1\alpha}$ levels, PGI_2 caused no consistent alteration in plasma renin activity.

Clinical implications: Intravenous PGI_2 (to a maximal dose of 10 ng/kg/min) is well tolerated by patients with CAD and stable angina pectoris, producing systemic, pulmonary and coronary vasodilatation, a marked increase in plasma 6-keto $PGF_{1\alpha}$ concentrations and no effect on plasma renin activity. Its therapeutic value in patients with CAD and stable or unstable angina is uncertain and merits further investigation.

An Improving Prognosis Over Time in Medically Treated Patients With Coronary Artery Disease

DAVID B. PRYOR, MD, FRANK E. HARRELL, Jr., PhD, KERRY L. LEE, PhD, ROBERT M. CALIFF, MD, and ROBERT A. ROSATI, MD

The national mortality rate from coronary heart disease has decreased during the past decade, for reasons that are not yet clear. The mortality rate and the total number of cardiovascular events both decreased during the last 10 years in 1,911 medically treated patients with significant coronary artery disease. This decrease cannot be explained by less sick patients being referred for evaluation. This study suggests that at least part of the decrease in coronary heart disease mortality observed nationally is occurring in patients with established coronary disease. (Am J Cardiol 1983;52:444–448)

Recent reports have described a decrease in mortality from coronary artery disease (CAD) in the United States.[1–11] From 1968 to 1976, unadjusted mortality rates for CAD decreased 12% and the age-adjusted mortality rate decreased 21%.[12,13] The decrease represents a potential annual saving of 191,500 lives nationally.[14]

The cause of the decrease is not clear. It does not appear to be secondary to artifact or changes in the coding of death certificates.[5–7] Fewer people may be developing CAD, which would represent a decrease in incidence. Alternatively, patients with CAD may be living longer. This investigation examines the decreases that occurred over time in cardiovascular mortality and morbidity rates in a consecutive population of patients referred for coronary angiography, and presents evidence that the prognosis has improved for medically treated patients with angiographically documented CAD.

Methods

Patients: Our patient population and information system have been described in detail.[15–18] Briefly, from November 1969 to July 1981, significant CAD (defined as ≥75% luminal diameter obstruction of ≥1 coronary arteries[19]) was diagnosed in 1,911 consecutive medically treated patients with chest pain who were referred to the Duke University Medical Center for cardiac catheterization. Baseline information collected prospectively included multiple descriptors of the history, physical examination, chest roentgenogram, electrocardiogram, and cardiac catheterization. The baseline characteristics used in this study are shown in Table I. They included variables shown by previous analyses[16,17] to be independently associated with future cardiac events, except for arteriovenous oxygen difference, which was not determined during the entire study period. Follow-up information was collected prospectively at 6 months, 1 year, and annually thereafter, and was 99% complete.[16] In our analyses, the follow-up events of interest included both cardiovascular death and total cardiac events (cardiovascular death or nonfatal myocardial infarction). Validation of the accuracy of our follow-up procedures for recognizing nonfatal infarction has been described.[17]

Data analysis: *Decreases over time:* Our purpose was to determine whether fewer cardiovascular deaths and events were occurring over time in our population. We chose 3 methods of investigation. First, we compared the Kaplan-Meier[20] survival and event-free curves for patients seen during 2 study periods (before 1974 and from 1976 to 1979). Second, we determined the 1-year mortality and total cardiac event rates for patients in each year of the study. The estimates of the rates for each year were smoothed by averaging the rates for the particular year with the year before and the year after, since the number of patients seen each year was relatively small. Finally, we used Breslow's formulation[21] of the Cox proportional hazards regression model[22] to determine the association between when a patient entered the study (the year of catheterization) and the likelihood of that patient dying or having a cardiac event.

Controlling for referral bias: Decreases in event rates in our population could be due either to less sick patients being referred for evaluation or to decreases in mortality and events occurring in equally sick patients. The distinction is important if our results are to aid in interpreting the observed national trend. Fewer events occurring in equally sick patients over time implies that an improved case-fatality rate for patients

TABLE I Baseline Descriptors

Clinical
Age
Sex
Chest pain frequency
Nocturnal chest pain
Progressive chest pain
Preinfarctional chest pain
Variant angina
Congestive heart failure severity
Vascular disease (peripheral or cerebrovascular)
Risk factors (smoking, hyperlipidemia, hypertension, family history, diabetes mellitus)
Previous myocardial infarction (history or electrocardiographic evidence)
Ventricular gallop
Electrocardiogram
Premature ventricular contraction
Left bundle branch block
Nonspecific intraventricular conduction defect (QRS duration ≥0.12 second without left or right bundle branch block)
ST-T-wave changes
Chest roentgenogram
Cardiomegaly
Cardiac catheterization
Left ventricular performance
Contractility (normal, diffusely abnormal)
Anterior, apical, or inferior asynergy
Left ventricular end-diastolic pressure
Mitral insufficiency
Anatomy
Number of diseased vessels
Significant left main, left anterior descending, left circumflex, or right coronary artery lesions

with CAD is partly responsible for the national decrease. This conclusion could not be justified if the decrease in event rates in our population was due to changes in referral practices.

We chose to examine this issue in 2 ways. First, we determined whether changes in the population mix (as assessed by the baseline characteristics) had occurred that would affect the risk of mortality or a cardiac event. Second, we determined whether significant decreases in event rates were still present after we adjusated for changes in the population mix.

Changes in the population mix: Spearman's rank correlation was used to determine whether the prevalence of any of the baseline characteristics at the time of catheterization had increased or decreased over time. Not all characteristics affect how likely a patient is to have a cardiac event. In addition, the importance in predicting prognostic events among the characteristics varies. We previously analyzed 81 separate baseline characteristics[15–18] in this population to determine which variables are independently associated with future events (either cardiovascular death or total cardiac events). These variables are included among the baseline descriptors noted in Table I. We summarized the combined effect on mortality or total cardiac events of all the variables by a "hazard score" (see Appendix for details). The hazard score summarizes in 1 variable the net mortality risk for a patient based on all the important descriptors known about that patient at the time of referral for evaluation. One measure of assessing whether less sick patients were being referred over time was to determine whether the hazard score had changed significantly over time. This was done using the Spearman correlation coefficient.

Independent (adjusted) changes in event rates over time: To determine the independent effect on future events of when a patient was referred for catheterization, we repeated the Cox analyses described earlier, including the baseline descriptors noted in Table I as covariates or confounding factors.[16] The results of this analysis revealed whether significant decreases in mortality or total cardiac events occurred over time after controlling for any known changes in the population mix.

We were particularly concerned that the recent availability of cardiac catheterization and aortocoronary bypass surgery at the beginning of the study period may have introduced a backlog of substantially different patients. This was suggested by a longer duration of symptoms for patients referred during the first year. Although previous analyses[16,17] have shown no independent effect of the duration of a patient's symptoms on future events, we were concerned that some unrecognized, prognostically important variables may have been present in these patients. Therefore, we repeated the Cox analyses excluding patients seen before July 1971. The analyses quantitated the trends present in the 1,807 consecutive medically managed patients who were catheterized from July 1971 to July 1981.

The magnitude of the decrease: We estimated the magnitude of the decreases by calculating the ratio of the estimated 1-year mortality and event rates in 1978 and 1971. The magnitude of the decrease after adjusting for any population differences was obtained from the adjusted Cox analyses (see previously). The relative risk of mortality and the relative risk of having a cardiovascular event for patients entering the study population in 1978 compared with those entering in 1971 were estimated from the ratio of the hazard functions for these 2 times of entry into the study. The ratios of the hazard functions were also calculated using the results of the analyses that excluded the first 1.5 years of data.

Results

In the follow-up to date, 530 patients have had cardiac events and 383 cardiovascular deaths have occurred. If only patients catheterized after July 1971 are considered, 472 patients have had cardiac events, including 338 cardiovascular deaths.

Decreases over time: Figures 1 and 2 show the Kaplan-Meier empirical survival and event-free curves for all patients evaluated from 1970 to 1973 and from 1976 to 1979. At all times during the follow-up period, fewer deaths and cardiovascular events have occurred in patients seen later than in those seen earlier. Figure 3

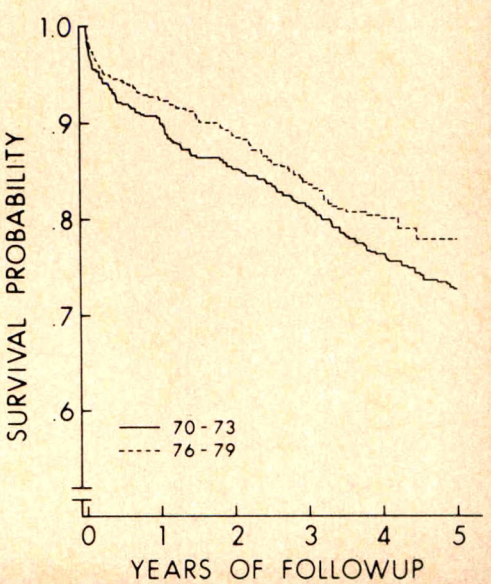

FIGURE 1. Survival probability (Kaplan-Meier) for patients first evaluated for different time periods.

shows the estimated 1-year mortality and total cardiac event rates as a function of each successive year of entry. Mortality and total cardiac events have progressively decreased during the study period.

Changes in the population mix over time: Table II illustrates the changes over time in the prevalences of the baseline characteristics. Although the prevalences of many of the baseline characteristics at the time of catheterization had changed significantly ($p < 0.05$), the individual changes were small. Some changes tended to increase the risk and others tended to decrease it, counterbalancing the effect on mortality. While statistically significant changes occurred, their clinical importance for prognosis was negligible. The significant changes themselves should be viewed with some skepticism because of the multiple number of comparisons performed. If the 37 characteristics were independent of each other, 2 significant ($p < 0.05$) changes would be expected by chance alone. The overall net risk, or hazard score, did not change significantly over time ($p = 0.34$).

Independent (adjusted) changes in event rates over time: The preceding analyses demonstrate significant decreases in event rates that are not explained by changes in the population mix. We would expect, then, that independent decreases in event rates had occurred over time in our population. The results of the Cox analysis (Table III) support this conclusion. Significant decreases in mortality and total cardiac events are present before and after controlling for baseline differences in the population over time. Decreasing trends in mortality and total events were also present, although less significant, when only patients seen after July 1971 are included.

The magnitude of the decrease: The estimated 1-year mortality rate in 1971 was 9.75% and the estimated 1-year cardiac event rate was 15.58% (Fig. 3). In 1978, the corresponding rates were 7.84% and 13.28%. For a patient first seen in 1978, the 1-year risk of dying was 80% of that for a patient evaluated in 1971. The 1-year risk of having any cardiac event for patients evaluated in 1978 was 85% of the risk for patients evaluated in 1971. The magnitude of the decreases estimated from the adjusted Cox analyses were similar: a relative hazard ratio for patients entering in 1978 compared with 1971 of 0.66 for mortality and 0.71 for total events (95% confidence intervals 0.47, 0.94 and 0.54, 0.94, respectively). When the adjusted trends excluding the first 1.5 years of data were used, the relative hazard ratio for patients entering in 1979 compared with 1972 was 0.67 for mortality and 0.75 for total events (95% confidence intervals 0.45, 1.00 and 0.55, 1.04, respectively).

Discussion

This study documents a decrease in both mortality and total cardiac event rates over the past decade in a patient population with well-characterized CAD. The decrease does not appear to be due to less sick patients being referred for evaluation. Decreases are present even after adjusting for the slight changes in baseline characteristics that occurred during this period and excluding the early patients from the analyses. Thus, the decrease is not attributable to a patient selection bias, with the sicker patients being referred for surgery. Our findings suggest that at least part of the national decrease in CAD mortality results from an improved survival for patients with CAD. This does not preclude a concurrent decrease in the incidence of CAD. We could not examine this hypothesis.

The magnitude of the decrease reported nationally reflects age-adjusted mortality rates in the entire United States population. The magnitude of the decrease estimated in our population includes only patients with documented CAD. These are not comparable. No attempt has been made to estimate how much of the national decrease may be a result of patients with established CAD living longer. The significance of our findings is limited to showing, in our population, that patients with established CAD are living longer and having fewer events.

Previous reports of changes in survival patterns over time have not included detailed information on the extent or severity of CAD. Our findings support reports from Rochester, Minnesota, based on comprehensive

TABLE II Changes* in the Prevalences of Baseline Characteristics Over Time

Increased	No Change	Decrease
Age (0.11)	Progressive chest pain (−0.004)	Males (−0.06)
History of smoking (0.08)	Preinfarction chest pain (−0.01)	Nocturnal chest pain (−0.16)
History of hypertension (0.10)	Variant angina (0.01)	Chest pain frequency (−0.07)
Family history (0.11)	Congestive heart failure (class IV) (−0.03)	Hyperlipidemia (−0.08)
History of MI (0.07)	Peripheral vascular disease (0.04)	Systolic blood pressure (−0.16)
ST-T-wave changes (0.13)	Cerebral vascular disease (0.04)	Ventricular gallop (−0.05)
Anterior LV asynergy (0.17)	History of diabetes mellitus (0.04)	ECG PVCs (−0.06)
Apical LV asynergy (0.17)	ECG Q waves (0.03)	ECG LBBB (−0.07)
Inferior LV asynergy (0.14)	ECG intraventricular conduction defect (0.04)	Normal contractility (−0.08)
LVEDP (0.11)	Cardiomegaly (−0.01)	Number of diseased vessels (−0.16)
Mitral insufficiency (0.09)	Diffusely abnormal contractility (−0.02)	Significant left main stenosis (−0.10)
	Significant RCA stenosis (0.01)	Significant left circumflex stenosis (−0.08)
	Hazard score or overall net risk (−0.02)	Significant left anterior descending stenosis (−0.07)

* Changes = Spearman correlation $p < 0.05$.
Spearman correlation coefficients shown in parenthesis.
ECG = electrocardiographic; LBBB = left bundle branch block; LV = left ventricular; LVEDP = left ventricular end-diastolic pressure; MI = myocardial infarction; PVC = premature ventricular contraction; RCA = right coronary artery.

TABLE III Changing Prognosis Over Time (Cox Model Statistics* Unadjusted and Adjusted Decreases)

Analysis	Outcome†	
	Survival	Total Events
All patients		
Unadjusted	6.47 (0.011)	11.93 (<0.001)
Adjusted‡	5.18 (0.023)	5.84 (0.016)
Patient entering after 7/1/71		
Unadjusted	3.57 (0.059)	6.98 (0.008)
Adjusted‡	3.77 (0.052)	3.00 (0.083)

* All values are expressed as chi squares (1 degree of freedom) with corresponding p values measuring the association between when a patient was referred for evaluation and future events.
† The dependent variable for survival was the time until a cardiovascular death. Total events refers to the time until a cardiovascular death or nonfatal myocardial infarction.
‡ Adjusted refers to inclusion of baseline descriptors in Table I as covariates (see text).

community health records that demonstrated a decrease in both incidence and case-fatality rates.[23,24] The magnitude of the decrease they reported in 1-year mortality (50%) from 1965 to 1975 in patients with clinically evident CAD appears to be similar to our own, although without invasive characterization it is difficult to compare the 2 populations. A report from a large prepaid health plan[25] revealed that from 1971 to 1977, the number of persons hospitalized for acute myocardial infarction decreased, but the proportion of deaths among those admitted did not change. The author of that report characterized his finding as a decrease in incidence with no change in the case-fatality rate. A "case" in that study however, referred to acute myocardial infarction rather than angiographically defined disease. In addition, the follow-up period was limited to the period of hospitalization. Long-term follow-up study might have revealed improved survival for patients discharged after acute myocardial infarction, as suggested by many of the beta-blocker trials.[26,27]

Because most patients with CAD live, the reduction in risk for an individual patient in a given year is quite small despite the apparent magnitude of the decrease. For example, if a patient seen in 1971 has an 8% risk of dying in 1 year, a similar patient seen in 1978 might have only a 6.4% risk of dying (80% of 8%), or a change per year of <1% (1.6% decrease in 7 years).

Our analyses demonstrate a method for controlling for selection bias introduced by changes in a population over time. Any investigation designed to determine whether a change in outcome in a population has occurred should address the issue of whether the change is due to a selection bias of which patients are enrolled. The Cox model analysis that adjusts for the covariates that affect the outcome event of interest is a powerful technique capable of identifying changes in outcome that may be due to the combined effect of relatively small changes in individual characteristics.[28,29] Other investigators may wish to use a similar technique to control for possible selection bias introduced by changes in their patient population over time.

We attempted to control for prognostically important sources of bias that might have been present in our population over time. We were particularly concerned that the recent availability of cardiac catheterization and aortocoronary bypass surgery at the start of our data collection may have initially introduced a backlog of substantially different patients. For that reason, we analyzed our results a second time, excluding the first 1.5 years of data and examining the adjusted trends in our population from mid-1971 through 1981. Because the ability of Cox analyses to detect changes is dependent in part on the number of events that occur and the length of follow-up, we would expect the significance of the analyses excluding the first 1.5 years of data to decrease. Decreasing trends (although not always significant at the 0.05 level) were still present in mortality and total cardiac events. Although reassuring, these results cannot exclude the possibility that an unrecognized source of chronology bias[30] existing beyond this period may have influenced our results.

Acknowledgments: We acknowledge the assistance of Charles B. McCants, Jr., Nancy Terry, Cristy Vollmar and Madelyn Farrell, who assisted in the preparation of this manuscript, and Drs. Joseph C. Greenfield, Jr. and Mark Hlatky for their careful review and helpful suggestions.

Appendix

Using the hazard score to summarize mortality risk: The mortality risk for a patient can be represented by a "hazard score." The hazard score summarizes in 1 variable the net contribution of all prognostically important baseline descriptors to the mortality risk for a patient. Using Breslow's formulation[21] of the Cox proportional hazards regression model,[22] and including all pertinent baseline descriptors as covariates or confounding factors,[16] the independent contribution to survival of each of the baseline descriptors can be quantitated. The hazard score is then calculated as: $B_1 X_1 + B_2 X_2 + \ldots B_n X_n$, where $X_1, \ldots, X_n$ = the baseline descriptors and $B_1, \ldots, B_n$ = their corresponding Cox regression coefficients. At any particular time t, the predicted survival S(t) can be calculated as $S(t) = S_0(t)^{\exp h}$, where $S_0(t)$ = the estimated survival probability with all variables set equal to their means and h = the hazard score.

Directional ST-Segment Deviation in Graded Exercise Tests Correlated With Motion of the Individual Segments of the Left Ventricular Wall

JAMES N. KARNEGIS, MD, PhD, JOHN MATTS, PhD, NAIP TUNA, MD, PhD, KURT AMPLATZ, MD, RICHARD B. MOORE, MD, HENRY BUCHWALD, MD, PhD, and the POSCH* Group

An exercise test may be characterized as positive because of the production of either electrocardiographic ST-segment depression or elevation. The relationship of exercise-induced ST-segment deviation to the specific motion abnormalities of the individual segments of the left ventricular wall was investigated. The first 280 subjects to enter the Program of Surgical Control of Hyperlipidemia were studied by treadmill exercise testing and left ventriculography. The results showed that exercise-induced ST-segment elevation could occur without evidence in the resting subject of either dyskinesia or aneurysm of the left ventricle, that the area of left ventricular damage was much greater in subjects with exercise-induced ST-segment elevation than in those with ST-segment depression, and that wall motion abnormalities were concentrated in the inferoposterior area in the group with ST-segment elevation, but were generally scattered throughout the left ventricular wall in the group with ST-segment depression.

(Am J Cardiol 1983;52:449–452)

A positive exercise test is generally considered to indicate the presence of myocardial ischemia. The interpretation that the test is positive chiefly depends on recording at least a minimal specified deviation of the ST segment of the electrocardiogram (ECG) during or immediately after exercise, compared with the position of the ST segment on the control tracing. Although the positive test is usually characterized by depression of the ST segment with exercise, in some persons it may become elevated instead. An exercise-induced elevated ST segment may possibly be associated with a left ventricular (LV) aneurysm or dyskinetic area,[1] but little is known about the specific abnormalities of motion of the individual LV segments and their relation to directional changes of the ST segment. Therefore, we analyzed LV segmental wall motion in subjects in the Program of Surgical Control of Hyperlipidemia (POSCH) who developed either ST-segment elevation or depression during a graded treadmill exercise test.

Methods

POSCH is a study of the effect of reducing the level of blood lipids on the natural history of the atherosclerotic disease process in hyperlipidemic subjects. Partial ileal bypass has been used in the management of hyperlipidemia since 1962; this procedure is the modality of intervention in the treatment group because it provides maximal reduction in blood lipid levels.

POSCH subjects at the time of entry into this secondary intervention clinical trial were 30 to 64 years of age, with 1 myocardial infarction documented by enzymatic and electrocardiographic criteria, a blood cholesterol level of ≥220 mg/dl, a systemic arterial pressure of <180/105 mm Hg, no other cardiac disease, and no other serious illness. The protocol excluded from the study subjects with a LV aneurysm detectable on physical examination or thoracic roentgenography. Baseline evaluation included selective cine left ventriculography and a graded exercise test. The LV wall in the right anterior oblique view was divided from the superior aspect clockwise into 3 anterolateral segments (numbered 1 through 3) and 3 inferoposterior segments (numbered 4 through 6) (Fig. 1). The movement of each segment was recorded as normal (normal inward movement of the various segments of the LV wall in systole), hypokinetic (reduced inward movement of the segments in LV systole), akinetic (no systolic movement of the segments) or dyskinetic (outward movement of segments in LV systole). A LV aneurysm was defined as a circumscribed dilatation or bulge in both ventricular systole and diastole. The ejection fraction was also calculated from the left ventriculogram.

The graded exercise test used the Bruce protocol modified by the addition of a 3-minute stage 0 (1.7 mph, 0% grade). Subjects were exercised until symptom- or sign-limited. A positive test was defined as an exercise-induced ≥1 mm depression or elevation in the ST segment of any lead in the electrocardiogram 80 ms after the J point compared with the proceeding PR segment in ≥3 consecutive beats. The ST segment may be isoelectric, elevated or depressed in relation to the PR segment as recorded on the control tracing before

exercise. In this research project, a 15-lead ECG (leads I, II, III, CS_5, aVL, aVF, V_1 through V_6, X, Y and Z) was recorded before and during recovery from exercise, and a 9-lead ECG (leads CS_5, aVL, aVF, V_4 through V_6, X, Y, and Z) was recorded during exercise. Lead CS_5 is a bipolar recording from the V_5 and right arm electrodes.

Statistical significance between the ST-depressed and the ST-elevated groups with respect to abnormal and normal numbers was assessed using Fisher's exact test for 2 × 2 tables. The International Mathematics and Statistical Library subroutine on the University of Minnesota Cyber 730 was used. The p values are the probability of achieving a 2 × 2 table as extreme or more extreme than the observed data.

For the difference in medians the 2 groups were divided into the number in each group with a value less than or equal to the population median and the number with a value greater than the population median. These data were placed in a 2 × 2 table and tested by Fisher's exact test as just described.

Results

We report here the baseline data from the first 280 subjects to enter POSCH. Of these, 127 (45%) had a positive graded exercise test as defined herein, 116 with a depressed and 11 with an elevated ST segment. Fifty percent (58 of 116) of those who developed ST-segment depression with exercise and 100% (11 of 11) of those who showed exercise-induced ST-segment elevation had abnormal Q/QS patterns according to the Minnesota Code for resting electrocardiograms.[2] The abnormal Q/QS pattern was located in the anteroseptal area of the heart in 36% (42 of 116) of the ST-depressed group and in 91% (10 of 11) of the ST-elevated group. The Q/QS abnormality in the remaining subject of the ST-elevated group was recorded in the inferoposterior area. In the ST-elevated group, 9 of the 10 subjects with abnormal anteroseptal Q/QS patterns showed some elevation of the ST segment on the resting ECG in the same lead showing the Q/QS abnormality; in the remaining case and in the subject with an abnormal Q/QS pattern in the inferoposterior area, the ST segment was isoelectric on the resting tracing. Of the subjects who had an abnormal Q/QS pattern in the anteroseptal area on the resting ECG and who also developed ST-segment deviation with exercise, 19% (10 of 52) showed ST-segment elevation and 81% (42 of 52) showed ST-segment depression. Four of the 11 who had exercise-induced ST-segment elevation simultaneously developed ST-segment depression in other leads.

TABLE I Total Number of Left Ventricular Segmental Wall Motion Abnormalities by Direction of Exercise-Induced ST-Segment Deviation

Abnormal LV Segments (n)	ST-Segment Depression		ST-Segment Elevation	
	n	%	n	%
0	42	36.2	0	0.0

6	3	2.6	0	0.0
Total	116	100	11	100
Median (p <0.004)	1		3	

LV = left ventricular.

TABLE II Percent of Individual Left Ventricular Segments With Motion Abnormalities by Direction of Exercise-Induced ST-Segment Deviation

LV Segment	ST-Segment Depression (n = 116)	ST-Segment Elevation (n = 11)	p
Anterolateral 1	23.5	0.0%	NS
Anterolateral 2	5.3	9.1%	NS
Anterolateral 3	17.7	54.5%	<0.01
Inferoposterior 4	22.1	81.8%	<0.001
Inferoposterior 5	24.8	81.8%	<0.001
Inferoposterior 6	38.9	63.6%	NS

LV = left ventricular; NS = not significant.

On left ventriculography none of the 127 subjects showed an aneurysm and none showed dyskinesia of the LV wall. LV segmental wall motion abnormalities were limited to hypokinesia or akinesia, or both. Table I summarizes the distribution of the total number of LV segmental wall motion abnormalities in both the ST-depressed and the ST-elevated positive graded exercise test subjects. Thirty-six percent of the ST-depressed group but none of the ST-elevated group had normal contraction of all 6 LV segments. The median number of LV segments with abnormal motion was 1 for the ST-depressed group and 3 for the ST-elevated group (p <0.004).

Table II shows the percent of the ST-depressed and ST-elevated groups who displayed abnormality of motion in each of the 6 segments of the left ventricular wall. Anterolateral segment 2 was infrequently involved in either group. Of the remaining segments, LV segmental wall motion abnormalities were roughly equally distributed in the ST-depressed group, but clustered in the inferoposterior area in the ST-elevated group. The difference between the 2 groups was statistically significant (p <0.01) for segment 3 and very highly significant (p <0.001) for segments 4 and 5.

The ECG lead in which the positive test with the greatest ST-segment shift was recorded is listed for both groups in Table III. Bipolar chest lead CS_5 and lead V_4 accounted for most of the positive recordings in both the ST-depressed and the ST-elevated group. Lead CS_5 was

TABLE III Electrocardiographic Leads Showing Exercise-Induced ST-Segment Deviation: Positive Graded Exercise Test Group

	ST-Segment Depression		St-Segment Elevation	
ECG Lead	n	%	n	%

TABLE IV Percent of Electrocardiogram Leads Positive for Graded Exercise Test by Motion Abnormalities of Individual Left Ventricular Segments

	Left Ventricular Segment					
Positive Graded Exercise Test ST-Segment Depression	1	2	3	4	5	6
Percent of subjects diagnosed from lead V_4 (n = 15)	40	13	13	20	27	40
Percent of subjects diagnosed from lead CS_5 (n = 72)	19	1	12	18	21	39

TABLE V Percent of Electrocardiogram Leads Positive for Graded Exercise Test by Motion Abnormalities of Individual Left Ventricular Segments

	Left Ventricular Segment					
Positive Graded Exercise Test ST-Segment Elevation	1	2	3	4	5	6
Percent of subjects diagnosed from lead V_4 (n = 8)	0	12	62	100	100	50
Percent of subjects diagnosed from lead CS_5 (n = 2)	0	0	0	50	50	100

the positive lead in 62% and lead V_4 in 13% of the ST-depressed group, whereas lead CS_5 was the positive lead for 18% and lead V_4 for 73% of the ST-elevated group.

Table IV shows, for the ST-depressed group, the percent of those whose test was interpreted as positive according to either lead V_4 or lead CS_5 and who showed motion abnormalities in the individual segments of the LV wall. Neither lead V_4 nor lead CS_5 indicated predictably motion abnormalities of the various LV segments.

Table V shows for the ST-elevated group the percent of those whose test was interpreted as positive according to either lead V_4 or lead CS_5 and who showed individual LV segmental wall motion abnormalities. All 8 of the positive cases judged by lead V_4 had abnormal motion of segments 4 and 5, and 5 and 4 of these 8 cases also showed abnormal motion of segments 3 and 6, respectively. Both of the positive cases according to lead CS_5 had abnormal motion of segment 6, with each showing additional involvement of either segment 4 or 5.

Discussion

The appearance of ≥1 mm of elevation in the ST segment during or immediately after exercise is relatively infrequent. In the first 280 POSCH subjects, exercise-induced ST-segment elevation occurred in 11 (3.9%). Chahine et al[3] reported a similar figure of 3.5%. The frequency of exercise-induced ST-segment elevation may be expected to depend, among other things, on the composition of the population studied.[4]

ST-segment elevation with exercise may be related to several factors, including a discrete LV aneurysm,[3] aneurysmal bulging in an area of localized myocardial ischemia,[1] severe ischemic cardiac disease,[5,6] and Prinzmetal's variant angina.[7]

ST-segment elevation with exercise is reported to be variably associated with a LV aneurysm. When studied by cardiac fluoroscopy in 1 reported series, an aneurysm was present in 33% of patients with exercise-induced ST-segment elevation,[8] and in another study of such patients, left ventriculography demonstrated a LV aneurysm in 86%.[3] In contrast, none of our subjects had an aneurysm on left ventriculography, which was not surprising because the protocol excluded from the study subjects with evidence of a LV aneurysm or its sequelae, as already described herein. Evidently, the screening process had effectively eliminated such subjects. The LV segmental wall motion abnormalities in our subjects were limited to hypokinesia or akinesia. In particular, none of those who developed ST-segment elevation with exercise showed dyskinesia of any of the various segments of the LV wall as judged by left ventriculography performed with the subject at rest. Although this finding does not support the concept that exercise-induced ST-segment elevation is related to left ventricular dyskinesia, it clearly does not exclude it because transient dyskinetic areas could possibly develop during the period of exercise.

Both the number of LV segments showing abnormal wall motion and their distribution differed in subjects with exercise-induced ST-segment elevation compared with those with ST-segment depression (Tables I and II). LV damage was greater in the group with ST-segment elevation and was mostly concentrated in the inferoposterior area, whereas the abnormal segments showed no particular localized distribution in the group with ST-segment depression. The number of abnormal segments correlated with the ejection fraction, the details and analysis of which will be reported separately.

Exercise-induced ST-segment elevation was not a necessary consequence of an abnormal Q/QS pattern because the latter was present in half of those who developed ST-segment depression with exercise. Similarly, the presence of an abnormal Q/QS pattern located specifically in the anteroseptal area was not a determinant in the development of ST-segment elevation with exercise because 81% of cases with these 2 features showed exercise-induced ST-segment depression.

The observation of LV segmental wall motion abnormalities in the inferoposterior area of the left ventricle in our subjects who had electrocardiographic ev-

idence of anteroseptal myocardial damage and who developed ST-segment elevation with exercise indicates that these subjects had widespread and severe coronary occlusive disease and is consistent with the data of Cabin and Roberts.[9] These investigators, in a quantitative analysis of coronary arterial disease in patients with healed myocardial infarction, found that of those who had had an anterior myocardial infarction, 95% had severe narrowing (76 to 100%) of >1 coronary artery and 50 and 95%, respectively, had severe narrowing of the left circumflex and right coronary arteries.

The predominant electrocardiographic lead detecting the greatest exercise-induced ST-segment elevation was lead V_4 and, to a much lesser extent, lead CS_5 (Table III). These frequencies were reversed in the ST-depressed, with lead CS_5 and, to a lesser extent, lead V_4 most commonly showing the greatest exercise-induced ST-segment depression. Leads V_4 and CS_5 correlated with inferoposterior myocardial damage in the ST-elevated group (Table V) but did not help in localizing LV segmental wall motion abnormalities in the ST-depressed group (Table IV).

Thirty-six percent of the group that developed ST-segment elevation during exercise showed a simultaneous depression in the ST segment in another lead. This finding suggests that exercise-induced ST-segment elevation may, at least in part, be a reciprocal electrical phenomenon, but it is probably also in some manner related to the large area of myocardial damage, as evidenced by the wall motion abnormalities concentrated in the inferoposterior portion of the left ventricle.

Only one has an absorbent pad.

Nitro-Dur™ (nitroglycerin) Transdermal Infusion System is the only transdermal nitroglycerin that contains an integral absorbent pad. We added it because adhesion may be affected by perspiration due to exercise or stress.

The absorbent pad is only one of several innovative design elements of Nitro-Dur. These elements help insure consistent, reliable drug delivery for a full 24 hours, dose after dose.

An integral absorbent pad. Another reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing a range of dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies using healthy volunteers,[1] transdermal absorption of nitroglycerin from Nitro-Dur achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Detectable plasma levels were attained within 30 minutes after application of the unit, and were still detectable 30 minutes after removal of the unit.

INDICATIONS AND USAGE: This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by,
Lawrence H. Cohn, MD,
Vincenzo Gallucci, MD

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

Contributors from virtually every major cardiovascular center in the world that has had any meaningful experience with cardiac bioprosthetic valves participated in this symposium where 45 papers were presented in 8 categories.

ISBN 0-914316-34-6, 596pp., illus., 1982, $65.00

Atlas Of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Foreword by David H. Spodick, MD

Dr. Alfredo Palacio has drawn on his rich experience to produce an atlas which presents in the simplest, most direct way possible the broadest range of normal and abnormal 2-dimensional echograms. Its excellent illustrations are complemented by beautiful drawings and supplemented by diagrams and explanatory texts which transcend the usual collection of illustrative material to explain methodology and provide the reader with a true "how-to-do-it" text. The descriptions and detailed illustrations in its technical sections should ensure the superior level of performance of echocardiographic techniques that is a *sine qua non* for good results.

Rehabilitation In Ischemic Heart Disease

edited by William P. Blocker, MD, David Cardus, MD

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 52 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; legal responsibilities of the physicians and therapists, and much, much more.

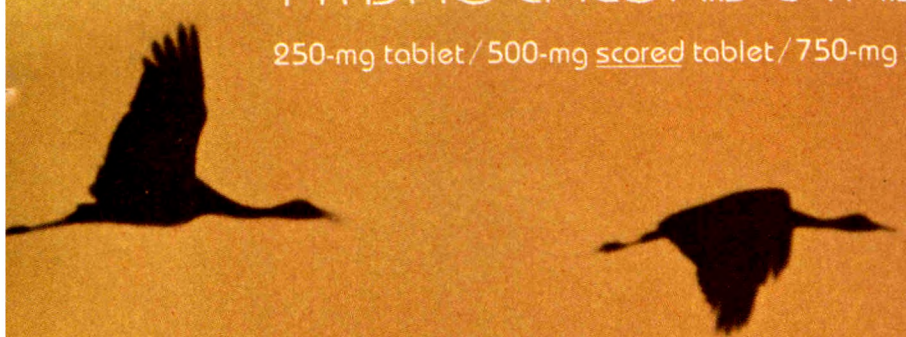
Return to a natural cardiac rhythm

SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet / 500-mg scored tablet / 750-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

If in the past you have substituted another medication for maintenance therapy because of compliance problems with conventional oral procainamide, now you can logically turn to the modern oral procainamide.

Procan SR... the original sustained-release oral procainamide

Please see next page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: General —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

ADVERSE REACTIONS: Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: Procan SR 250 mg (green, film-coated tablet. P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet. P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet. P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).

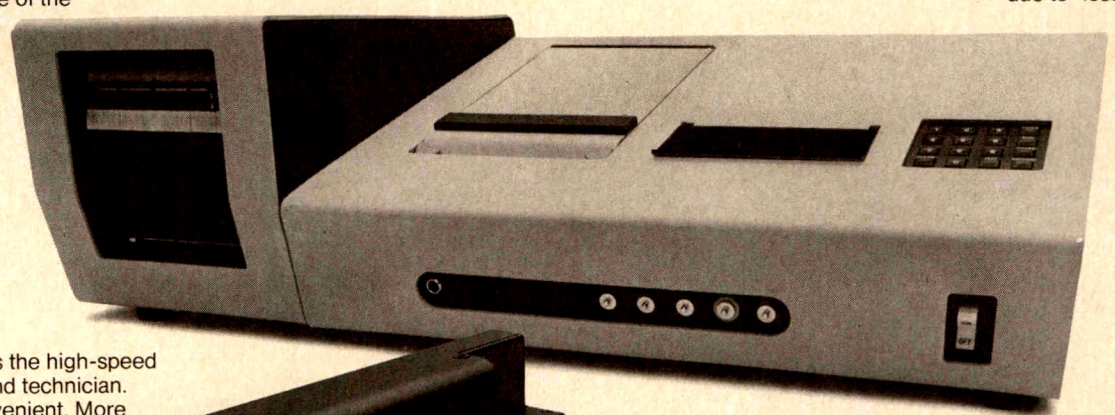
Clinical evaluation of various systems for analysis of ambulatory ECG records has been difficult to implement due to the variety of approaches to recording data, the operator-dependence of traditional recording and interpretation systems, and the subjective clinical judgements necessary in using the final results. One manufacturer can now report data utilizing a real-time approach to ambulatory monitoring that compares clinical accuracy to hand-counted data as a standard.[1]

In Holter studies, AEGIS™ gives you results in minutes... right in your office... without a specially trained operator.

Provides the same clinical information as a scanning service—with none of the drawbacks.

• Fits easily into any office.

• System validates itself—no need for repeat studies due to "lost" data or faulty equipment.



• Replaces the high-speed scanner and technician. More convenient. More efficient.

• Puts the control of evaluating Holter studies directly into your hands. Provides time-stamped rhythm strip and summary report for your confirmation.

• Analyzes each heartbeat as it occurs; counts and categorizes arrhythmias in real time.

For a 15-minute, no obligation demonstration, call toll-free: 800-257-5750.

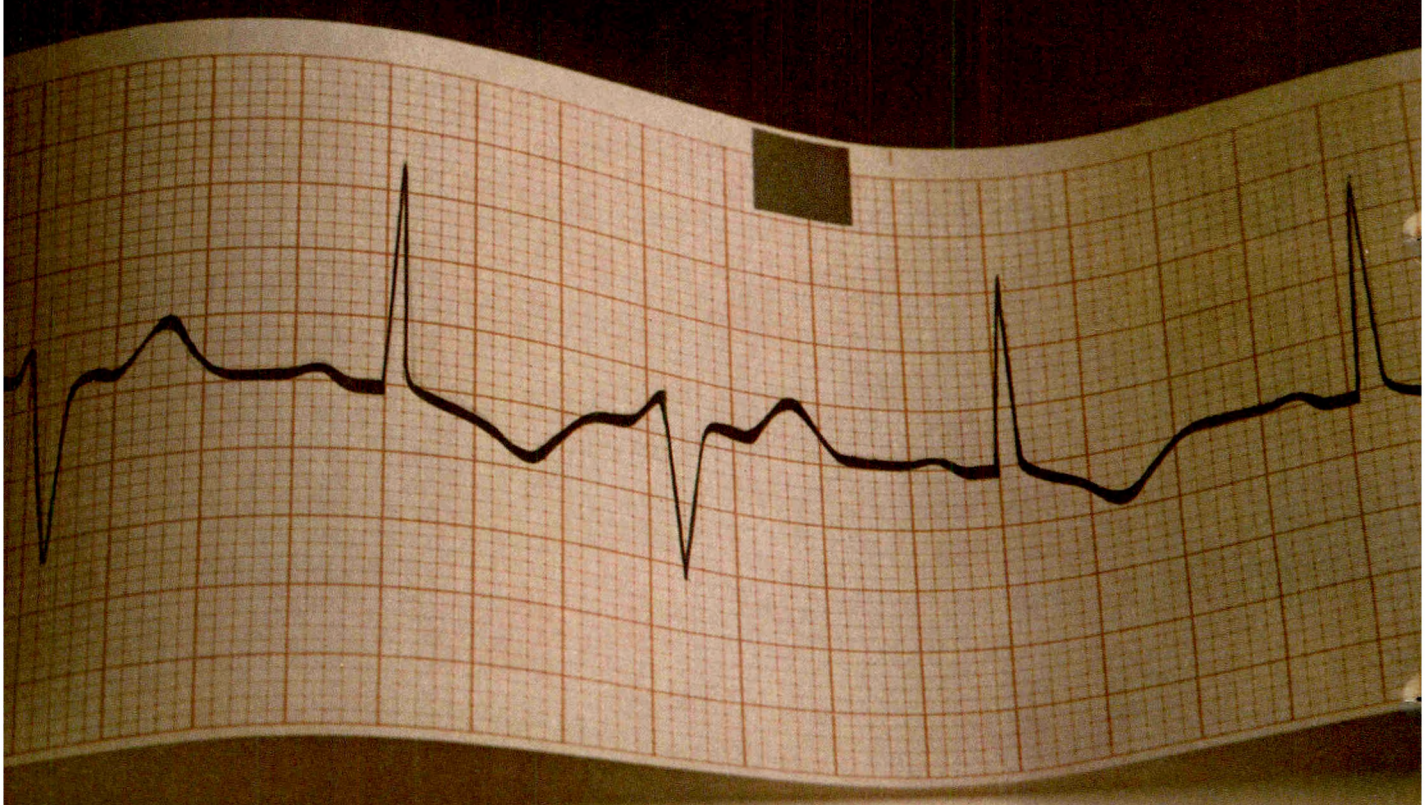
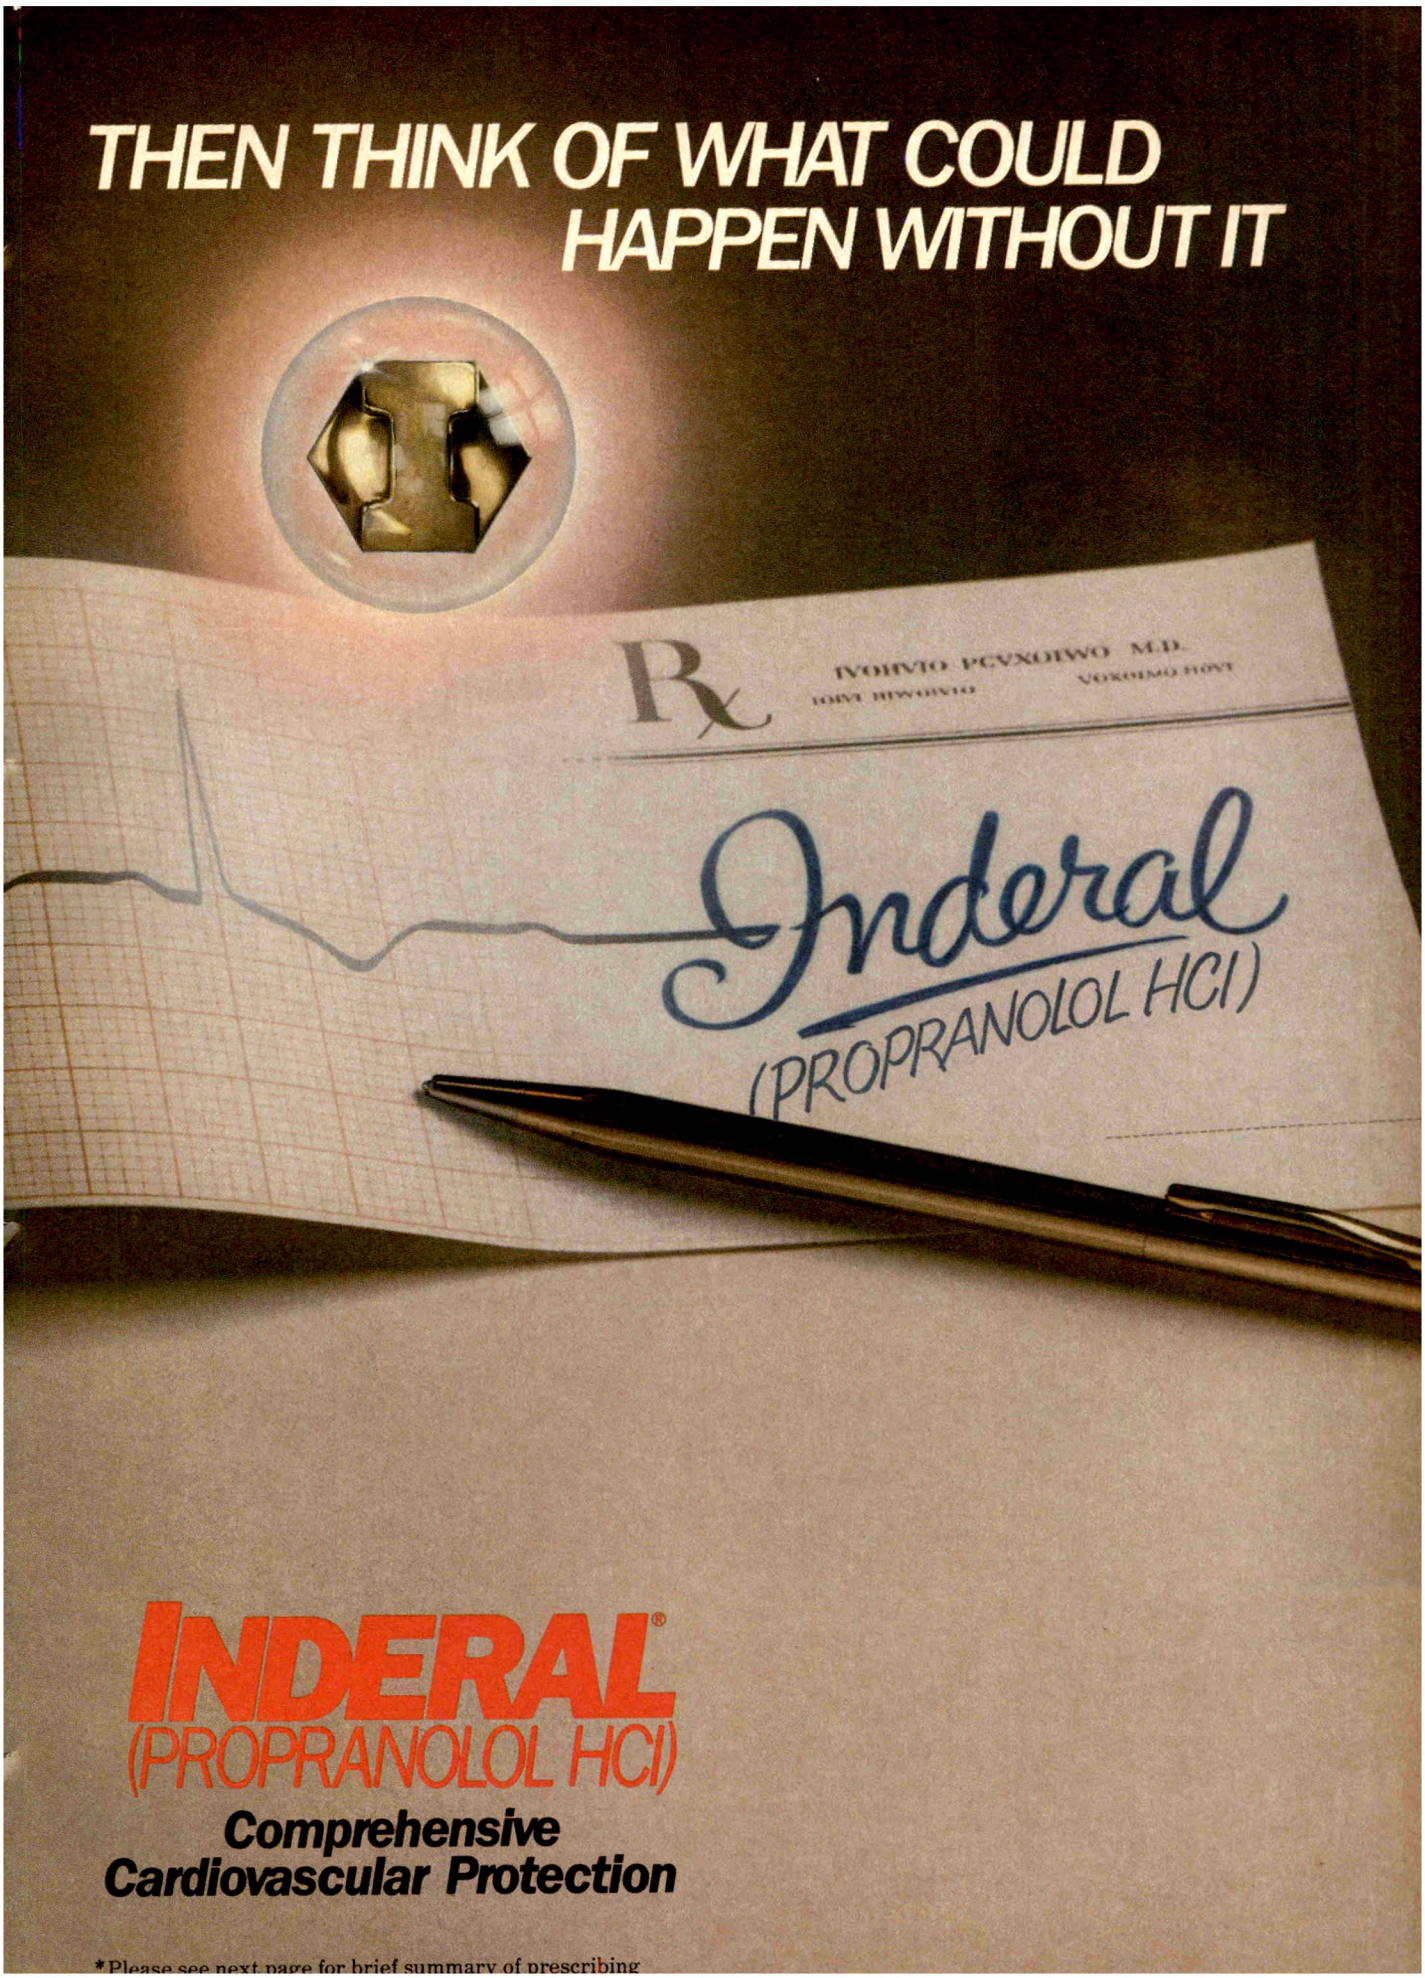
ARRHYTHMIAS
FIRST THINK OF INDERAL®
(PROPRANOLOL HCl)



Inderal—a primary agent for the control of many arrhythmias.

INDERAL is effective in a broad range of arrhythmias. Consider INDERAL first for a variety of supraventricular arrhythmias. While ventricular arrhythmias do not respond as predictably as supraventricular arrhythmias, INDERAL is often considered as drug of first choice for ventricular arrhythmias induced by catecholamines or digitalis.

INDERAL is uniquely suited for long-term prophylaxis...it is an antiarrhythmic agent that offers a particularly favorable side effects profile*...and INDERAL is the only beta blocker indicated for the treatment of arrhythmias *and* coexisting angina and hypertension.



THEN THINK OF WHAT COULD HAPPEN WITHOUT IT

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

Propranolol hydrochloride is contraindicated in 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. Propranolol acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by propranolol's negative inotropic effect. The effects of propranolol and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during propranolol therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of propranolol therapy. Therefore, when discontinuance of propranolol is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when propranolol is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If propranolol therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute propranolol therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long-term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since propranolol is a competitive inhibitor of beta-receptor agonists, its effects can be reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), propranolol should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of propranolol in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if propranolol is administered. The added catecholamine-blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of propranolol may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains **10 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains **20 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains **40 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, pink, scored tablet is embossed with an "I" and imprinted with "INDERAL 60," contains **60 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0426-81) and 1,000 (NDC 0046-0426-91). Also in unit dose package of 100 (NDC 0046-0426-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains **80 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

Hemodynamic Effects of Felodipine at Rest and During Exercise in Exertional Angina Pectoris

JEAN-MARIE R. DETRY, MD, PATRICK M. De COSTER, MD, and JEAN RENKIN, MD

To examine the antianginal effects of felodipine, a new calcium antagonist, 8 patients with coronary artery disease and exertional angina pectoris were studied. Hemodynamic measurements were made at rest, during submaximal exercise and during angina-limited exercise before and 30 minutes after oral administration of 0.1 mg/kg of felodipine. Angina pectoris was always prevented after the drug was given and the exercise intensity was increased until recurrence of angina (5 patients) or exhaustion (3 patients). Hemodynamic data were also recorded at this higher exercise capacity. At rest and during submaximal exercise, felodipine increased heart rate and decreased arterial blood pressure and systemic vascular resistance. The prevention of angina pectoris was accompanied by lower mean pulmonary capillary wedge pressure, systemic vascular resistance and ST-segment depression; the pressure-rate product was unchanged. The 20% greater exercise capacity after felodipine was attended by a 20% increase in maximal cardiac output, a 17% increase in maximal heart rate and a 13% increase in maximal pressure-rate product; the maximal arterial blood pressure and ST-segment abnormalities were unchanged and the systemic vascular resistance was lower. The relation between ST-segment depression and the pressure-rate product during exercise was favorably influenced by felodipine.

Thus, felodipine is an active antianginal drug; its major mechanism of action is to lower the systemic vascular resistance. The data also suggest that it improves coronary blood flow during exercise.

(Am J Cardiol 1983;52:453–457)

Felodipine (4-(2,3-dichlorophenyl)-1,4-dihydro-2,6-dimethyl-3,5-pyridine dicarboxylic acid ethyl methyl-ester) is a newly developed calcium antagonist that, like nifedipine, is a dihydropyridine. Pharmacologic studies indicate that felodipine acts selectively on vascular smooth muscle, but its effects on the myocardium are less marked than those of nifedipine.[1–3] Previous clinical studies have shown that felodipine is a potent and well tolerated antihypertensive agent,[4,5] but little is known about its antianginal effects. The present study examines the antianginal effects of felodipine in a group of patients with exertional angina pectoris. Hemodynamic data were collected at rest and during submaximal and maximal exercise before and after 0.1 mg/kg of felodipine given orally.

Methods

Patients: Eight patients (6 men and 2 women, mean age 58 years) who had disabling and exertional angina pectoris were studied. The presence of significant coronary lesions was documented in all cases (Table I). Patients with a history of heart failure or systemic hypertension were excluded from the study; beta blockers and calcium antogonists were discontinued at least 48 hours before the start of the study. No serious complications occurred as a result of the experimental protocol.

Protocol: The patients first performed a multistage bicycle exercise test in the sitting position; the initial work load of 20 W for 1 minute was increased by 20 W each minute. Exercise was continued until the onset of typical angina pectoris. Electrocardiographic leads V_4, V_5 and V_6 were monitored on an oscilloscope and recorded on paper every minute during exercise and during the first 5 minutes of recovery. The electrocardiographic tracings were analyzed visually. The amount of horizontal ST-segment depression was measured 0.08 second after the J point, with the PR interval used as 0 reference. The main objective of this multistage exercise test was to determine the level of exercise that induced angina pectoris. This information served to determine the intensity of the exercise levels to be used during the hemodynamic study.

The next day, hemodynamic variables were measured with patients in supine and sitting positions at rest and during 2 levels of sitting exercise; each level lasted 5 minutes (Fig. 1). The intensity of the first level was well below the threshold for angina. The intensity of the highest exercise level was selected from the results of the first exercise test so that angina was induced after 3 to 4 minutes. Thus, hemodynamic data were obtained at rest, during submaximal exercise and during

exercise-induced angina. After these measurements were completed, the patients rested in a supine position for 1 hour. After 30 minutes of rest, the patients were given felodipine orally (0.1 mg/kg of body weight).

Thirty minutes after felodipine was administered, the protocol was repeated. The hemodynamic variables were measured when the patients reached, without developing angina, the work level that had precipitated angina before felodipine treatment. The work load was then increased by 10 W/min until angina pectoris or the first signs of exhaustion appeared. That level of exercise was maintained for 5 minutes until hemodynamic measurements were completed (Fig. 1).

Hemodynamic measurements: Cardiac output was measured as previously described[6] at rest and during the last minute of each exercise period using the Fick principle. Briefly, a No. 7 Swan-Ganz balloon-tip catheter was percutaneously induced in the basilic vein and floated in the pulmonary artery; a small Teflon® catheter was introduced in the brachial artery. The pressures were measured during the 20 seconds preceding the cardiac output measurements with Statham P23Db transducers.

Precautions were taken to control factors that might influence the response to exercise.[6] The experiments were performed in the air-conditioned room with a temperature of 22 ± 1°C and relative humidity of 50 ± 10%.

Hemodynamic variables were calculated as follows: pressure-rate product = heart rate × systolic brachial pressure × 10^{-2}; systemic and pulmonary resistances = mean pressure × 80/cardiac output; and stroke work = stroke volume × mean brachial pressure × 1.36 × 10^{-2}.

The significance of differences was analyzed with a Student paired t test and McNemar test.

Results

Exercise capacity: The individual data on maximal exercise capacity are presented in Table II. Before felodipine administration, all patients were limited by exertional angina pectoris at a low exercise level (66 W). After felodipine, the symptom-limited maximal oxygen consumption increased from 1093 to 1314 ml/min (20%; $p < 0.001$), the maximal heart rate increased from 113 to 132 beats/min ($p < 0.001$) and the maximal systolic blood pressure was about the same, 157 versus 152 mm Hg (difference not significant [NS]). The pressure-rate product at maximal exercise increased significantly after felodipine, from 177 to 200 mm Hg/min^{-2} ($p < 0.02$), while the electrocardiographic abnormalities slightly but insigificantly decreased. All patients performed more work after felodipine and 3 were no longer limited by angina pectoris.

Hemodynamics at rest: At rest, the body position (supine or upright) did not influence the direction of the hemodynamic changes after felodipine, although these changes tended to be more marked and of greater statistical significance in the upright position. After felodipine, in the upright position, the cardiac output increased from 5.9 to 6.6 liters/min ($p < 0.001$) and the heart rate from 71 to 79 beats/min ($p < 0.001$). The systolic arterial blood pressure decreased from 138 to 126 mm Hg ($p < 0.001$) and, consequently, systemic vascular resistance was markedly reduced from 1480 to 1125 dynes s cm^{-5} ($p < 0.001$). The pressure-rate product and the mean capillary wedge pressure did not change.

Hemodynamics at submaximal exercise: The changes after felodipine during submaximal exercise were similar to those at rest. The heart rate increased from 96 to 109 beats/min ($p < 0.005$) and cardiac output from 8.4 to 9.2 liters/min (NS); the systolic arterial blood pressure decreased from 142 to 132 mm Hg ($p < 0.005$) and systemic vascular resistance from 987 to 851 dynes s cm^{-5} ($p < 0.02$). The pressure-rate product and the mean capillary wedge pressure did not change.

Changes in hemodynamics at maximal exercise: The work load that caused angina pectoris during the control study was always performed without pain after felodipine was administered. The prevention of angina pectoris was accompanied by a significant decrease in

the mean capillary wedge pressure (from 24 to 19 mm Hg; $p < 0.05$) (Fig. 2). The heart rate increased from 113 to 119 beats/min ($p < 0.10$) and the systolic arterial pressure decreased from 157 to 146 mm Hg ($p < 0.02$); because these changes were in opposite direction, the pressure-rate product did not change. The electrocardiographic signs of myocardial ischemia were significantly reduced (ST depression from 2.1 to 1.3 mm; $p < 0.005$).

At the higher exercise level (Fig. 2, Table II), the increased oxygen consumption after felodipine was a result of the greater maximal cardiac output (from 9.3 to 11.2 liters/min [20%], $p < 0.05$), which was explained by a higher maximal heart rate, the maximal stroke volume was not modified. The maximal systolic blood pressure insignificantly decreased after felodipine and the maximal pressure-rate product increased. The ST-segment depression at maximal exercise insignificantly decreased after felodipine, from 2.1 to 1.8 mm.

Electrocardiographic changes during exercise: The relation between the ST-segment depression and pressure-rate product (Fig. 3) was altered by felodipine. After drug administration, there was a significantly smaller ST-segment depression for a similar pressure-rate product or the ST-segment depression was unchanged despite higher values of the pressure-rate product.

Discussion

Our data indicate that felodipine has a significant antianginal effect. The exercise level that induced angina pectoris in all patients during the control study was always reached without pain 1 hour after felodipine was administered. Furthermore, after felodipine, all patients exercised at a higher level and 3 patients were no longer limited by angina. Felodipine induced a 20% increase in physical working capacity; this improvement is similar to that usually observed after other calcium antagonists[7–12] or after nitrates.[6,13] The major hemodynamic modification underlying this antianginal effect appears to be a decrease in systemic vascular resistance.

The protocol of the hemodynamic study included a first period of light exercise followed by a higher work load that induced angina pectoris in all patients within 4 to 5 minutes. When this protocol was repeated 60 minutes later, the reproducibility of the measurements was good for cardiac output, stroke volume, central pressures during exercise and pressure-rate product at the level of angina pectoris.[6,14,15] The hemodynamic modifications observed in our study can thus be safely attributed to the effect of felodipine and not to a placebo effect or to the simple repetition of the exercise test.

Hemodynamic effects during rest and exercise: The major effect of felodipine is to decrease the systemic vascular resistance. The lower blood pressure was attended by an increase in cardiac output and by a significant tachycardia. This increase in heart rate, suggesting a baroreceptor-mediated reflex, explains the lack of change in the pressure-rate product at rest and during exercise. Similar hemodynamic changes have been reported after nifedipine, a drug that increases heart rate and cardiac output and decreases systemic vascular resistance, while the pressure-rate product is usually unchanged.[16–18] These data differ from those collected after the administration of other calcium antagonists such as verapamil or diltiazem, which reduced the pressure-rate product at rest and during submaximal exercise.[7–10]

Prevention of angina pectoris: After receiving felodipine, all of our patients reached, without pain, exercise levels that had induced angina pectoris during the control period. At this exercise level, the exercise electrocardiogram was significantly improved and the filling pressure of the left ventricle was significantly reduced. These changes after felodipine indicate clearly that myocardial hypoxia was delayed, although the pressure-rate product was not significantly lower at that exercise level. Similar hemodynamic data have been reported for the effect of nifedipine.[19,20] At this level of exercise, the major mechanism of action of verapamil or ditiazem appeared to be a decrease in the rate-pressure product.[7–10]

Increased exercise tolerance: After felodipine, the exercise capacity of all of our patients was improved, and 3 of the patients were no longer limited by angina. This greater physical capacity was explained by the significantly higher maximal heart rate and maximal cardiac output. At the highest exercise level after felodipine, systolic blood pressure was similar to the control value and the maximal pressure-rate product was thus significantly greater than during the control period. This increase in the maximal pressure-rate product, while the ECG and hemodynamic abnormalities were not affected, suggests that the myocardial oxygen supply might have been improved by felodipine. This hypothesis is also supported by the change in the relation between the pressure-rate product and ST-segment depression.[21] Several investigators have reported that the improved exercise capacity of anginal patients after nifedipine was accompanied by an unchanged or increased maximal pressure-rate product together with a decrease in the ECG or scintigraphic signs of myocardial ischemia.[19,22–24] These results are best explained by an improved maximal coronary blood flow. Engel et al[25] showed that coronary flow to the ischemic zone was probably improved by nifedipine. After verapamil and diltiazem, the maximal pressure-rate product is probably unchanged, while the electrocardiographic abnormalities have been reported to be unchanged[7,10] or decreased[8,9] at the maximal exercise level. These findings have also been interpreted as suggesting that coronary blood flow is enhanced by calcium antagonists.

Morphology of Ventricular Premature Beats as an Aid in the Electrocardiographic Diagnosis of Myocardial Infarction

HAROLD DASH, MD, and THOMAS J. CIOTOLA, MD

To determine whether morphologic analysis of ventricular premature beats (VPBs) can aid in the electrocardiographic diagnosis of myocardial infarction (MI), 12-lead electrocardiograms were evaluated in 760 consecutive patients who underwent cardiac catheterization, and 2-minute multiple-lead rhythm strips were evaluated in 515 of these patients. VPBs occurred in 58 patients; 21 had prior MI diagnosed by regional akinesia or dyskinesia on left ventricular cineangiography. Standard criteria were used to diagnose prior MI from the sinus beats of the electrocardiogram. Infarction was diagnosed from the morphology of a VPB when it had a QR or QRS pattern with Q wave ≥0.04 second.

Morphologic analysis of VPBs had a low sensitivity (29%) but high specificity (97%) and high predictive value (86%) for the diagnosis of MI. Sinus beats diagnosed MI with higher sensitivity (52%, and 69% if patients with left bundle branch block and left ventricular hypertrophy were excluded from analysis) than VPB morphologic analysis ($p < 0.05$), but with similar specificity (97%) and predictive value (92%). Two patients with angiographic MI had no MI according to standard electrocardiographic criteria, but did have an MI manifest by VPB morphologic analysis. Despite low sensitivity, analysis of the morphology of VPBs may be useful for the diagnosis of MI when the morphology of sinus beats is not diagnostic. Therefore, VPB analysis is complementary to the standard electrocardiographic diagnosis of MI.

(Am J Cardiol 1983;52:458-461)

In 1943, Dressler[1] reported that the morphology of ventricular premature beats (VPBs), by demonstrating pathologic Q waves, allowed him to make the electrocardiographic diagnosis of an acute myocardial infarction (MI) in a patient with left bundle branch block. Since his initial report, other anecdotal studies[2-6] have described the diagnosis of acute and healed MI from electrocardiographic morphologic analysis of VPBs. Although Bisteni et al[7] correlated the morphology of VPBs with experimental MI, the usefulness of this electrocardiographic sign has not been systematically studied in a population of patients at risk for cardiac disease. Moreover, there have been case reports of autopsy-proved false-positive diagnoses of MI from morphologic analysis of VPBs in patients with tuberculous pericarditis,[8] cor pulmonale[9] and valvular heart disease.[9] Consequently, we evaluated the relation between the morphologic characteristics of VPBs, baseline electrocardiographic findings, and the presence of MI identified at cardiac catheterization to document the value of VPB analysis in the diagnosis of old MI.

Methods

Patients: We examined the electrocardiograms of 760 consecutive adult patients who had undergone diagnostic cardiac catheterization at the Milton S. Hershey Medical Center from December 1979 through February 1981. All patients had electrocardiograms the day before catheterization. The last 515 patients also had 2-minute, multiple-lead rhythm strips. Fifty-eight patients demonstrated VPBs and constitute the study population.

Cardiac catheterizations: All patients had coronary angiography performed by either the brachial or femoral approach. Significant obstructive coronary artery disease was defined as a stenosis of >70% luminal diameter. Of the 58 patients with VPBs, 33 had biplane left ventricular cineangiography and 25 had single-plane left ventricular cineangiography in the 30° right anterior oblique projection. Angiograms were evaluated by an investigator who had no knowledge of the clinical diagnosis or electrocardiographic findings. Left ventricular regional wall motion was evaluated qualitatively, and an angiographic diagnosis of MI was defined as a localized region of asynergy that showed akinesia or dyskinesia.[10,11]

Electrocardiographic analysis: Electrocardiograms were analyzed without knowledge of the clinical history or angiographic findings. Standard criteria[12] for the electrocardiographic diagnosis of MI from sinus beats were used: Anterior infarcts included those with pathologic Q waves ≥0.04 second in leads V_1 to V_3 (anteroseptal) or V_2 to V_4 (anteroapical). Lateral infarcts included those with pathologic Q waves in leads I, aVL and V_5 to V_6. Inferior and posterior infarcts included those with a Q wave ≥0.04 second and ≥25% of QRS deflection in lead aVF (inferior), or slurred R wave ≥0.04 second with R/S >1 in lead V_1 (posterior). When pathologic Q waves were present in the setting of other conditions that could account for the QRS abnormalities, such as left bundle branch block and left or right ventricular hypertrophy, MI was not diagnosed.

VPBs were defined according to the criteria of Chung.[13] MI was diagnosed from VPB analysis according to previously established criteria[4,12]: whenever a VPB showed a qR or qRS configuration with q wave ≥0.04 second. Lead aVR was excluded from analysis.

Statistical analysis: For the evaluation of the morphologic characteristics of VPBs, true-positive studies included those that met VPB criteria for an MI and had an angiographic diagnosis of MI. True-negative studies were those in patients without MI by VPB analysis and angiography. False-positive studies were those with an MI by VPB but not on angiography. False-negative studies denoted cases with an angiographically documented MI but no MI by VPB analysis. Similar criteria were used to correlate the diagnosis of MI based on sinus beats of the electrocardiogram with the data obtained from cardiac catheterization. For VPBs and sinus beats, sensitivity, specificity and predictive values were defined as follows: *sensitivity* = true positives/(true positives + false negatives); *specificity* = true negatives/(true negatives + false positives); and *predictive value* = true positives/(true positives + false positives).

The ability to diagnose MI by VPB morphologic analysis compared with sinus beats was evaluated by chi-square analysis with Yates' correction.

Results

Clinical characteristics: Of the 760 patients initially evaluated, 461 had coronary artery disease, 145 valvular heart disease, 16 primary dilated cardiomyopathy and 20 congenital heart disease; 118 patients were normal. Of the 58 patients with VPBs on the electrocardiogram, 29 had coronary artery disease, 27 had other cardiac disease and 2 were normal (Table I).

MI was documented at cardiac catheterization in 21 of 29 patients (72%) with coronary artery disease. All 21 patients had a region of akinesia or dyskinesia on the left ventriculogram with a total or subtotal occlusion of the coronary artery supplying the abnormal area. All 21 patients had a history of prolonged chest pain at rest; 14 were hospitalized at the time of pain and MI was confirmed by an abnormal increase in cardiac enzymes. Four of the 7 patients without enzymatic confirmation of MI had documentation by myocardial scintigraphy or necropsy. Two patients had MI diagnosed by redistribution thallium scintigraphy, and the location of MI corresponded to the region of asynergy seen on angiography. Two patients died within 1 week of catheterization and had old MI confirmed at autopsy, with the locations correlating to the areas of angiographic abnormality. The diagnosis of old MI independent of the angiographic or electrocardiographic data could not be confirmed in 3 patients.

TABLE I Clinical Characteristics of Patient Population

(prior myocardial infarction)	(21)
Valvular heart disease	23
Dilated cardiomyopathy	3
Congenital heart disease	1
Normal	2
Total	58

Electrocardiographic analysis: Comparative sensitivity, specificity and predictive values for the diagnosis of MI from sinus beats and VPBs are given in Table II. MI was diagnosed from sinus beats of the electrocardiogram in 11 of 21 patients (sensitivity 52%). If the 5 patients with electrocardiograms that masked the diagnosis of MI (left bundle branch block in 2, left ventricular hypertrophy in 3) are excluded, the sensitivity of the electrocardiographic diagnosis of MI from sinus beats increases to 69%. There was a false-positive electrocardiographic diagnosis of MI (specificity 97%) in a patient with congenital subaortic stenosis. The predictive value of the standard electrocardiographic criteria for the diagnosis of MI was 92%.

MI was diagnosed by morphologic analysis of VPBs in 6 of 21 patients (sensitivity 29%). Three patients did not have VPBs in an electrocardiographic lead corresponding to the angiographic location of their MI. If these 3 patients are excluded from analysis, the sensitivity of the VPB criteria for the diagnosis of MI increases only to 33%. One patient without angiographic evidence of MI had VPBs with a morphology indicative of infarction (specificity 97%). He had severe aortic

TABLE II Value of Electrocardiography and Ventricular Premature Beat Morphologic Analysis in the Diagnosis of Myocardial Infarction

	ECG	ECG*	VPB	VPB*
Sensitivity	11/21 (52%)	11/16 (69%)*	6/21 (29%)	6/18 (33%)*
Specificity	36/37 (97%)	—	36/37 (97%)	—
Predictive value	11/12 (92%)	—	6/7 (86%)	—

* $p < 0.05$ ECG* versus VPB.*

ECG = sinus beats of electrocardiogram; ECG* = sinus beats excluding those in electrocardiograms with left bundle branch block or left or right ventricular hypertrophy; VPB = ventricular premature beats; VPB* = VPBs excluding those in electrocardiograms in which premature beats did not occur in leads likely to reflect myocardial infarction. See text for explanation.

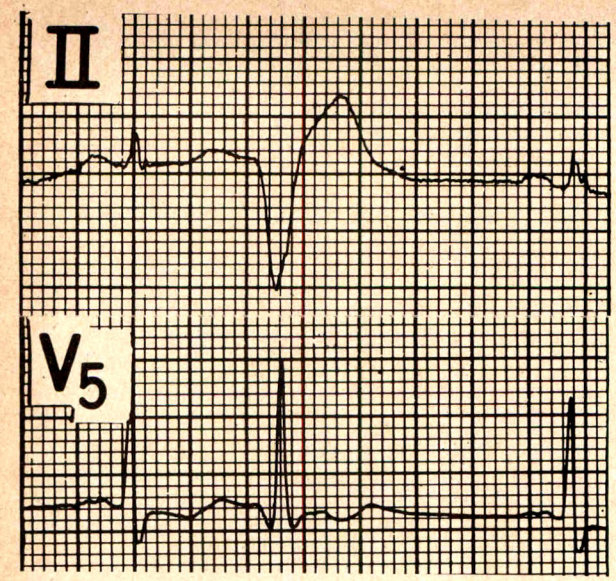

FIGURE 1. Simultaneous rhythm strip of leads II and V_5 from a patient with extensive inferolateral myocardial infarction at angiography. The 12-lead electrocardiogram was nondiagnostic for infarction, showing only a narrow Q wave in lead III. A ventricular premature beat in lead V_5 shows a QRS pattern with a pathologic Q wave.

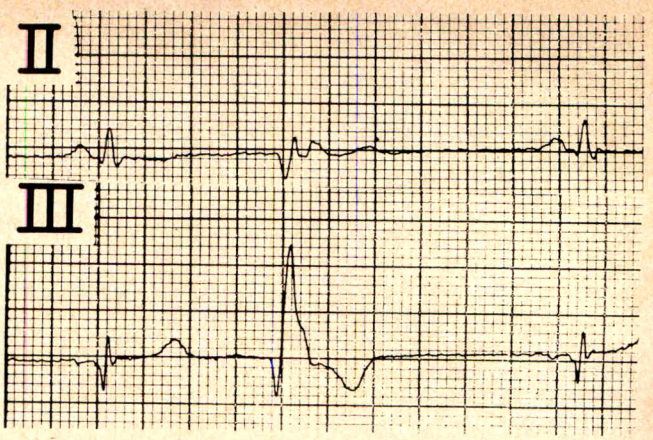

FIGURE 2. Simultaneous rhythm strip of leads II and III from a patient with a prior inferior myocardial infarction. The 12-lead electrocardiogram was nondiagnostic for infarction, with narrow Q waves in leads II, III and aVF and Q <25% of the total QRS deflection in lead aVF. The ventricular premature beat in leads II and III shows a QR pattern with a pathologic Q wave.

regurgitation, biventricular failure, and right atrial enlargement. The predictive value for the diagnosis of MI from the morphology of VPB was 86%.

There were no significant differences in the sensitivity, specificity or predictive value when comparing the two techniques in the diagnosis of MI. When the patients with left bundle branch block, left ventricular hypertrophy and no VPBs in the electrocardiographic leads corresponding to anatomic MI site are excluded from analysis, MI was diagnosed from sinus beats on the electrocardiogram with greater sensitivity ($p < 0.05$) than from VPB morphologic analysis.

Two patients with a documented MI did not have an MI on the sinus beats of the electrocardiogram, but had one according to VPB criteria. One had a large inferolateral MI at angiography with a totally occluded right coronary artery. A VPB in lead V_5 (Fig. 1) showed a pathologic QR pattern. The other patient had an inferior MI. VPBs in leads II and III had pathologic QR patterns (Fig. 2).

Discussion

Case reports,[1–3] while identifying the phenomenon of VPB morphologic characteristics suggestive of MI, do not determine the usefulness of the finding. Our results confirm that an analysis of the morphology of VPBs is highly specific for the diagnosis of MI and thus provides a complementary tool to the standard electrocardiographic diagnosis of MI. Such high specificity, however, depends on the use of strict criteria for making the diagnosis of MI from VPB morphology. Bisteni et al[7] showed in an experimental dog model that VPBs with QR or QRS pattern occurred only after MI, but that beats with a QS pattern could be produced in normal hearts.

Freundlich and Kavanagh-Gray[5] reviewed 20 electrocardiograms with VPBs that had a qR morphology suggestive of MI. Their patients had a history of angina or MI; 17 had an MI pattern on the sinus beats of the electrocardiogram, and the 3 others had an MI documented at autopsy. Although their study seems to confirm our findings of the high specificity of VPB morphologic analysis in the diagnosis of MI, they did not report the overall patient population from which they obtained their electrocardiograms. Anttonen et al[9] examined VPBs with qR patterns in the precordial electrocardiographic leads and found false-positive diagnoses of MI in 14 of 126 patients (specificity 89%). Twelve of these 14 patients had cor pulmonale or valvular heart disease and clinical evidence of right ventricular dilatation and right heart failure. Of interest, therefore, is a recent report[14] documenting marked right atrial enlargement as a cause of a qR pattern in the right precordial electrocardiographic leads. Our one patient with a false-positive diagnosis of MI by VPB morphologic analysis had severe aortic regurgitation with biventricular failure and right atrial enlargement documented at surgery.

Several limitations of our study should be mentioned. Despite the large number of patients accrued into the study, including 461 patients with coronary artery disease and many with prior MI, only 58 patients had VPBs. To identify more patients with prior MI and VPBs, it would be necessary to obtain multiple-lead rhythm strips over prolonged periods. Such a procedure would be cumbersome, impractical and costly.

Another potential limitation of our study was our method of identifying MI. Although akinetic and dyskinetic segments of myocardium usually correspond to transmural scar,[11] other investigators have demonstrated occasional improvement in regional contraction in such segments after administration of nitroglycerin[15] or after revascularization.[16] In our study all 21 patients with an MI defined angiographically had histories of

prolonged chest pain, and 18 had their MI confirmed independently by clinical history. Thus, it is unlikely that we had any false-positive diagnoses of MI.

Did we miss any MIs because 25 of the 58 patients did not have biplane left ventricular cineangiograms? No patient without an angiographic MI had a clinical history suggestive of MI. The only false-positive electrocardiogram was in a patient with congenital subaortic stenosis. The only false-positive MI by VPB morphologic analysis was in a patient with valvular heart disease. Both of these patients had biplane cineangiograms. It is doubtful, therefore, that we underdiagnosed MI in our patient population. In contrast, studies[6,9] of VPB morphology in the diagnosis of MI that relied on clinical history and laboratory data to diagnose MI probably underestimated the true incidence of MIs in their patient populations, because as many as 23% of MIs are unrecognized clinically.[17]

In conclusion, VPBs with morphologic characteristics indicative of MI occur infrequently; however, when they are seen, their high specificity and predictive value make them useful for the diagnosis of MI. The one major exception is the group of patients with right ventricular failure and right atrial enlargement in whom VPBs in the right precordial electrocardiographic leads may falsely suggest MI. Morphologic analysis of VPBs may be especially valuable when the resting electrocardiogram is nondiagnostic for MI, as in left bundle branch block, or, as is often the case, with an old inferior MI.

Prognosis After an Initial Non–Q-Wave Myocardial Infarction Related to Coronary Arterial Anatomy

MICHAEL R. NICHOLSON, MB, FRACP, GARY S. ROUBIN, MB, FRACP, LOUIS BERNSTEIN, MB, FRACP, PHILLIP J. HARRIS, MB, DPhil, FRACP, and DAVID T. KELLY, MB, FRACP

Eighty-six consecutive hospital survivors (aged ≤60 years) of a first non–Q-wave acute myocardial infarction (MI) were followed up prospectively. Coronary arteriography was performed a median of 2 weeks after MI. The size of the MI was small (as judged by a mean peak creatine kinase level of 906 IU/liter); 90% were in Killip class I, and the mean left ventricular ejection fraction was 60 ± 11% (± standard deviation). Forty-nine patients had 1 vessel significantly narrowed by disease (≥70% luminal diameter reduction), 19 had 2-vessel, 2 had 3-vessel, 3 had left main (≥50% luminal diameter reduction), and 13 minimal or no coronary artery disease (CAD). Complete occlusion of the MI-related vessel was present in 33 patients. All 33 and an additional 5 patients had collateral vessels to the MI area. During a mean follow-up of 25 months, 1 cardiac death and 4 recurrent infarcts (3 with non–Q-wave MI) occurred. Angina occurred in 53 patients (62%) and responded medically in all but 7 who underwent coronary artery surgery. Angina after MI occurred frequently in patients with severe proximal left anterior descending CAD (≥90%), and in those with CAD (≥50%) in a vessel supplying collaterals to the infarct area.

Because angina can be managed medically in most patients and the outcome is good, routine coronary angiography is not indicated in asymptomatic survivors ≤60 years of a first non–Q-wave MI. (Am J Cardiol 1983;52:462–465)

Non–Q-wave acute myocardial infarction (MI) characterized by electrocardiographic ST-T-wave changes without the development of pathologic Q waves is a common clinical syndrome in patients admitted to a coronary care unit. Such infarcts are not necessarily transmural or subendocardial.[1,2] The late mortality rate after non–Q-wave MI has been reported to be comparable with Q-wave MI,[3,4] and some studies have demonstrated a high incidence of early[5] and late[6,7] recurrent MI after an initial non–Q-wave MI. Because of this reported high incidence, patients who sustain a non–Q-wave MI have been recommended for early coronary angiography and, when appropriate, coronary artery bypass surgery.[8]

Despite recent reports of the outcome of patients with non–Q-wave acute MI, little information is available about their coronary artery disease (CAD) and its relation to prognosis. In this prospective study, hospital survivors ≤60 years of age with a first non–Q-wave acute MI underwent early coronary angiography, and subsequent clinical events were correlated with the extent and severity of coronary artery obstruction.

Methods

Patients: Between November 1976 and February 1982, 380 consecutive patients ≤60 years of age with no other life-threatening diseases were discharged from our coronary care unit after an acute MI. Of these, 121 had electrocardiographic evidence of non–Q-wave MI. Thirty-three patients with non–Q-wave MI were excluded from this study because of 1 or more of the following criteria: previous MI (n = 14), in-

TABLE I Coronary Angiographic Data

Number of Significantly Stenosed Vessels*	
Left main	3
3 vessels	2
2 vessels	19
1 vessel	49
0 vessel	13
Diameter reduction of IRV	
Occluded	33
>90 ≤99%	27
≥70 ≤90%	8
<70%	18
Collateral vessels present to IRV	38
Jeopardized collateral vessels† to IRV	17
Proximal LAD stenosis‡	20

* Luminal diameter reduction of ≥50% of left main or ≥70% of left anterior descending, circumflex or right coronary arteries.
† Arising from a vessel which is itself ≥50% stenosed.
‡ Left anterior descending arterial diameter reduction by ≥90% before the first septal or diagonal branch, or both.
IRV = infarct-related vessel; LAD = left anterior descending artery.

terhospital transfers (n = 17), cardiomyopathy (n = 3), and valvular heart disease (n = 1). Patients in whom infarct extension occurred in hospital were also excluded. Two eligible patients did not undergo angiography. Eighty-six survivors of a non–Q-wave MI form the study group. The age range was 27 to 60 years (mean ± standard deviation [SD] 49 ± 7).

Sixty-eight of the patients were men and 18 were women. Previous angina pectoris occurred in 52 (60%). Risk factors included 59 smokers, 28 with previously documented systemic hypertension, 9 with diabetes mellitus and 13 with a history of a parent or sibling who died of CAD at <55 years of age.

Non–Q-wave MI was diagnosed by a characteristic history of prolonged chest pain, an increase in serum creatine kinase levels to at least twice the normal level (MB isoenzymes were not routinely assayed) and the development of ST- or T-wave changes that persisted for at least 24 hours in the absence of pathologic Q waves. Q waves were considered pathologic if they were ≥0.03 second in duration and were one third or more of the R-wave amplitude.

Cardiac catheterization: Cardiac catheterization was undertaken a median of 2 weeks after MI (mean 3.8 ± 4.6, range 1 to 19). Ejection fraction was calculated from the 30° right anterior oblique left ventricular (LV) cineangiogram.[9] Significant coronary stenosis was considered present if there was ≥70% luminal diameter reduction of a major artery in any view or if there was ≥50% luminal diameter reduction of the left main coronary artery. All angiographic studies were reviewed by 3 experienced observers and reports were made by consensus.

Follow-up study: After hospital discharge, patients were attended by their own physicians and no attempt was made to influence their management. The mean duration of follow-up was 25 ± 18 months and was 100% complete.

Statistical evaluation of results and events was undertaken using the chi-square test. Pooled data are reported as mean ± 1 SD.

Results

The site of MI was anterior in 23 patients (27%), anterolateral in 31 (36%) and inferior in 32 (37%). Seventy-seven patients (90%) were in Killip class I, 6 were in class II and 3 were in class III. No patient developed cardiogenic shock. The mean peak creatine kinase measurement for the group was 906 ± 694, suggesting the infarct size was small. In the coronary care unit, 4 patients developed ventricular fibrillation or sustained ventricular tachycardia that required cardioversion.

Cardiac catheterization: The mean LV ejection fraction was 60 ± 11%. The details of CAD are shown in Table I. The infarct-related vessel was identified as the coronary artery supplying the area of abnormal contraction seen on the ventriculogram consistent with the electrocardiographically determined site of MI. In 33 patients this vessel was completely occluded. In these patients and in 5 with ≥90% stenosis of the infarct-related vessel, collateral vessels filled the infarct-related vessel beyond its proximal stenosis.

Clinical Outcome

Death: One patient died suddenly 14 months after an initial inferior infarct. At previous cardiac catheterization, 90% stenosis of the distal right coronary artery was present without other significant CAD. The ejection fraction was 58%. Stable angina pectoris occurred after hospital discharge and was controlled with beta-adrenergic blocking drugs. One noncardiac death occurred and was attributable to peritonitis.

Coronary artery bypass surgery: In 3 patients with left main disease and 1 patient with severe proximal left anterior descending (LAD) stenosis, surgery was undertaken within 1 month of cardiac catheterization. All 3 patients with left main CAD had severe angina in hospital after MI. In another 3 patients, surgery was undertaken later because of medically refractory angina. All 7 patients treated surgically are alive and free of angina a mean of 19 months after operation.

Recurrent myocardial infarction: Four patients had a late MI. In 3 it was a recurrent non–Q-wave MI in the area of the initial non–Q-wave MI. In the fourth patient, a Q-wave MI developed in the same area as the previous non–Q-wave MI. In 2 patients who experienced a recurrent MI in the same anatomic area as the original MI, early angiography demonstrated an occluded vessel supplying the infarct area.

Angina pectoris: Angina pectoris occurred after MI in 53 patients (62%). Neither hypertension nor cigarette smoking after MI were significantly related to angina after MI. However, 81% of patients who had angina before MI continued to experience angina after MI, whereas only 38% of patients without preinfarction angina experienced angina after MI ($p < 0.05$).

The extent and severity of CAD were related to angina after MI (Table II). Only 3 of 13 patients with insignificant coronary narrowing and 6 of 18 patients (33%) with <70% stenosis of the infarct-related vessel had post-MI angina. In contrast, 50 of 73 patients (68%) ($p < 0.05$) with significant (≥70% diameter reduction by disease) narrowing of ≥1 vessels and 47 of 68 patients (69%) ($p < 0.05$) with ≥70% stenosis of the infarct-related vessel had post-MI angina. The presence of severe proximal LAD disease (≥90% stenosis before the first septal perforator or first diagonal branch) and a jeopardized (≥50% stenosis) collateral blood supply to the infarct area appeared to be the most significant angio-

TABLE II Angiographic Data and Postinfarction Angina

Characteristic	n	Angina Present (%)	Angina Absent (%)	p Value
Multivessel disease*	24	19 (79)	5 (21)	<0.05

graphic predictors of post-MI angina. Eighteen of 20 patients (90%) with LAD stenosis and all 17 patients with jeopardized collateral blood supply developed post-MI angina.

Discussion

In these patients ≤60 years of age who survived a first non–Q-wave MI, only 1 cardiac death and 4 infarcts occurred during the 2-year mean follow-up period. They represent part of a larger series of patients with a good prognosis after MI.[10]

Angina pectoris after non–Q-wave MI occurred frequently but responded to medical therapy in most patients; 4 required surgery early and 3 later. All 3 patients with left main disease had medically refractory angina in the hospital after their initial MI and underwent early surgery. Angina was common in patients who experienced angina before MI. The most reliable angiographic predictors of angina after MI were severe proximal LAD disease or collateral vessels to the infarct area that arose from a stenotic artery.

Early exercise testing of the patients in this study was not routinely performed, but in our experience and in that of others it is a good predictor of patients who develop postinfarction angina.[11]

The outcome and extent of CAD in these patients is different from other reported series. This may be a result of different patient selection. All patients with previous MI or other significant cardiac or noncardiac disease and patients transferred from other hospitals because of complications were excluded from this study. Many studies of non–Q-wave MI have found a high rate of recurrent MI and cardiac death in the survivors, but have included patients with previous MI[3,4,6,7,12–15] and hospital-transferred patients.[4,6–8,13–16] The prognosis of patients who have had a previous MI is worse[17] and hospital transfer to a tertiary institution is usually for high-risk patients. Age is an important prognostic factor in CAD.[18] The mean age in our patients was 49 years, whereas in 2 previous studies the mean age was 66 and 63 years.[6,7] Other studies of younger patients with a first non–Q-wave MI revealed a prognosis similar to ours.[16,19]

Other studies have reported that the degree of LV impairment and the severity of CAD did not differ in patients with non–Q-wave and Q-wave MI, but again did not exclude those with previous MI.[8,14,20,21] A study comparable to ours showed that LV function is better and CAD less severe in patients with non–Q-wave MI.[22]

LV cineangiography in our patients demonstrated minimal impairment of LV function, suggesting that the size of the MI is small. Significant 1-vessel narrowing was found in 58% of patients and is partially explained by the younger age of the group and the fact that this MI was the first MI. The near-normal LV function and less severe CAD are the principal reasons that our patients have a good prognosis.

Clinical implications: Patients ≤60 years who survive a first non–Q-wave MI have a good prognosis. All 3 patients with significant left main CAD had severe MI after angina in the hospital and underwent operation. The patient who died and those who sustained late MI could not be retrospectively identified by knowledge of their CAD or LV function. Although angina pectoris after non–Q-wave MI was common, it was usually controlled satisfactorily by medical treatment. The degree and amount of CAD could not be predicted from the clinical data and was heterogeneous. Proximal LAD disease or jeopardized collateral vessels or both were usually associated with postinfarction angina.

Effects Induced on Blood Platelets in Ischemic and Nonischemic Myocardium

ERIK THAULOW, MD

The function of blood platelets sampled from the coronary sinus and the superior vena cava was studied in 50 men with coronary artery disease at rest and during pacing-induced angina. At rest, a lower platelet aggregation and retention response was found in coronary sinus compared with vena caval blood. This may be due to refractoriness after previous platelet stimulation or to release of platelet inhibitors in the coronary circulation. During pacing-induced angina, lactate levels indicated that blood was sampled from ischemic myocardium in only 27 of the patients. Pacing-induced angina influenced platelet function differently in blood from ischemic and nonischemic regions. Adenosine diphosphate- and collagen-induced aggregation, platelet retention and plasma beta-thromboglobulin levels remained unchanged in blood from ischemic myocardium during pacing, but increased in blood from nonischemic regions. Thus, factors other than ischemia activated platelets in the coronary circulation during tachycardia-induced stress.

(Am J Cardiol 1983;52:466–469)

Coronary artery thrombosis is not always found in acute myocardial infarction.[1] Coronary emboli, platelet microaggregates and arterial spasm have been suggested as causes of both transient and irreversible myocardial damage.[2,3] In a canine model,[4] the infusion of glass beads caused platelet microaggregation in the myocardial vessels and sudden death, which could be prevented by inhibition of platelet function.[4] Platelet aggregates have been found in epicardial arteries in patients who die suddenly,[5] suggesting that aggregates may have precipitated local ischemia and lethal arrhythmias. To examine the relation between coronary artery disease (CAD) and platelet function, blood has been sampled directly from the coronary sinus.[6–8] Differences in platelet function between parallel coronary sinus and aortic samples have been assumed to reflect changes induced in the coronary vessels, but the interpretation is difficult because general differences seem to exist in platelet function between arterial and venous blood.[9]

The present study compares platelet function in blood from the coronary sinus and the superior vena cava in patients with CAD to investigate effects of myocardial ischemia on platelet function. Atrial pacing was used to induce angina and lactate measurements to reveal myocardial ischemia.

Materials and Methods

Heart catheterization was performed in 50 men as part of an evaluation for bypass surgery. All patients had typical angina and ST-segment depressions on the electrocardiogram (ECG) during an exercise test. None had taken aspirin for the last 10 days or beta blockers and calcium antagonists for the last 5 days. The 18 patients who smoked abstained from smoking for 12 hours before catheterization. Coronary angiography revealed CAD of more than 75% luminal diameter of at least 1 of the major coronary arteries in all but 2 patients, in whom 50% stenoses were found. Angiography was not performed in 1 patient.

After each patient gave informed consent, cardiac catheterization was performed with multipurpose catheters (polyurethane [Cordis®], 100 cm long, No. 8Fr). One catheter was advanced to the coronary sinus under fluoroscopic control and an identical catheter was positioned in the superior vena cava. A pacing electrode (Cordis®) introduced to the right atrium was connected with an external pacemaker (Cordis®) to allow an increase in heart rate by 10 beats every 2 minutes until angina developed. The ECG was monitored continuously from the precordial lead that gave the most pronounced ST-segment depression during the exercise test. The heart rate achieved during that test was an indicator of the extent to which the pacing rate had to be increased, but end points of pacing were angina and significant ST-segment depression. A venflon (Viggo®) was positioned in a femoral artery to allow sampling of arterial blood for lactate measurements. All catheters were kept open with continuous infusions of saline. No heparin was added. Blood was collected simultaneously from the coronary sinus and the vena cava for platelet function tests at rest and during maximal pacing. The lactate levels were measured in arterial and coronary sinus blood before, at the end of and 15 seconds after pacing.

TABLE I Platelet Function in Blood From the Superior Vena Cava and From the Coronary Sinus Sampled at Rest From 50 Patients with Coronary Artery Disease

	Superior Vena Cava	Coronary Sinus	
	Mean ± SD	Mean ± SD	p
Primary, ADP-induced aggregation (abritrary units)	14 ± 7	12 ± 7	<0.001
Collagen-induced aggregation (arbitrary units)	30 ± 13	27 ± 14	=0.07
Platelet retention			
Method A (%)	37 ± 14	26 ± 15	<0.001
Method B (%)	51 ± 17	43 ± 20	<0.005
Platelet counts (platelets/μl × 10^{-3})	235 ± 70	239 ± 64	NS
Circulating platelet aggregates (ratio)	0.91 ± 0.15	0.93 ± 0.13	NS
Plasma levels of Beta-thromboglobulin (ng/ml)	74 ± 30	77 ± 28	NS
Platelet counts in PRP (platelets/μl × 10^{-3})	380 ± 122	376 ± 117	NS

ADP = adenosine diphosphate; NS = not significant; p = level of significance; PRP = platelet-rich plasma; SD = standard deviation.

The following platelet functions were measured: Platelet aggregation was induced in an aggregometer (Payton) in platelet-rich plasma (PRP).[10] PRP was produced by centrifugation of blood collected into tubes containing 0.1 *M* sodium citrate. Adenosine diphosphate (ADP), 1.5 μmol/l, and collagen, 5 ng/ml in final concentrations (both Sigma Chemical Co.), were used as inducers. The aggregation response was read as the maximal rate of the primary, ADP-induced or collagen-induced aggregation and was calculated in arbitrary units as previously described.[11] No corrections were made for variations in platelet counts,[10] since they were similar in parallel PRP samples both at rest and during pacing.

Platelet retention was measured with Hellem's modified technique,[12] counting the platelets before and after native blood was forced at a constant rate through a glass bead column. Using *Method A*, 0.9 ml of blood was examined; using *Method B*, 3.6 ml was examined. Platelet counts were determined in triplicate in an automatic Coulter counter.

Beta thromboglobulin (βTG) was measured with a radioimmunoassay (Amersham). Blood was sampled into precooled vials containing ethylene diamine tetraacetate (EDTA), theophylline and prostaglandin E_1.[13] Plasma was separated after centrifugation for 30 minutes at 2000 *g* and, subsequently, for 30 minutes at 5000 *g* before freezing and analysis.

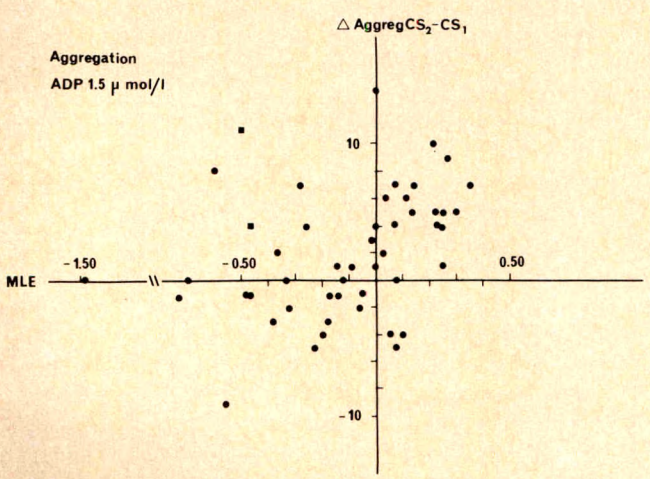

FIGURE 1. Relation between myocardial lactate extraction (MLE) during pacing and the difference between adenosine diphosphate–induced aggregation in coronary sinus blood at rest (CS_1) and during pacing (CS_2). Squares represent patients in whom the catheter was positioned rather distal in the coronary sinus.

The presence of circulating platelet aggregates in whole blood was estimated as described by Wu and Hoak.[14] A ratio of the platelet counts in PRP prepared with EDTA to platelet counts in PRP prepared with EDTA and formalin was determined. A ratio <1 reflects the presence of circulating platelet aggregates.

Lactate levels in plasma were measured to confirm whether ischemia was induced. Two milliliters of blood were added to precooled vials containing perchloric acid before centrifugation. The lactate levels were determined in triplicate.[15] Myocardial lactate extraction (MLE) was calculated as the difference between aortic and coronary sinus lactate levels divided by aortic lactate levels.

Statistics: The results are given as mean ± standard deviation. Differences between parallel or repeated measurements were determined with a Student *t* test. The coefficient of correlation was assessed with Hewlett Packard computerized programs and the coefficient of variation (CV) as described elsewhere.[16]

Results

All 50 patients had pacing-induced angina and 40 had ST-segment depression; net myocardial lactate production occurred in only 27. These 27 "ischemic" patients are considered separately because platelets were sampled from predominantly ischemic regions in them. In the ischemic patients the mean MLE at rest, during pacing and immediately after pacing was 0.19 ± 0.12, −0.13 ± 0.24 and −0.40 ± 0.33, respectively. In the 23 "nonischemic" patients, the corresponding values were 0.24 ± 0.10, 0.20 ± 0.05 and 0.15 ± 0.11. The heart rate during maximal pacing was 125.2 ± 13.7 beats/min in ischemic patients and 125.7 ± 15.0 beats/min in nonischemic patients.

At rest, the primary ADP-induced aggregation and the retention values were moderately but significantly lower in coronary sinus than in vena caval blood (Table I). The βTG plasma levels, platelet counts and circulating platelet aggregates were similar in the parallel venous samples.

Atrial pacing had no effect on platelet function in coronary sinus blood in the 27 ischemic patients (Table II). In the 23 nonischemic patients, however, platelets were activated, as judged from a 28% increase in ADP-induced aggregation, a 13% increase in collagen-induced aggregation, a 50% increase in platelet retention as measured with Method A, and a 26% increase in plasma

TABLE II Platelet Function in Coronary Sinus Blood at Rest and During Pacing-Induced Angina in 27 Patients in Whom Blood Was Collected From Ischemic Myocardium and 23 in Whom Blood Was Collected From Nonischemic Myocardium

	Ischemic Group			Nonischemic Group		
	Rest Mean ± SD	Angina Mean ± SD	p	Rest Mean ± SD	Angina Mean ± SD	p
Primary, ADP-induced aggregation (arbitrary units)	12 ± 7	12 ± 6	NS	12 ± 7	15 ± 9	<0.01
Collagen-induced aggregation (arbitrary units)	24 ± 14	24 ± 15	NS	31 ± 14	35 ± 15	NS
Platelet retention						
Method A (%)	30 ± 16	32 ± 15	NS	23 ± 13	34 ± 13	<0.005
Method B (%)	45 ± 20	48 ± 20	NS	41 ± 19	45 ± 18	NS
Platelet counts (platelets/μl × 10^{-3})	238 ± 81	232 ± 80	NS	239 ± 38	247 ± 54	NS
Circulating platelet aggregates (ratio)	0.87 ± 0.16	0.92 ± 0.12	NS	0.97 ± 0.15	0.78 ± 0.24	NS
Plasma levels of Beta-thromboglobulin (ng/ml)	76 ± 27	71 ± 23	NS	79 ± 29	99 ± 50	<0.05

ADP = adenosine diphosphate; p = level of significance; PRP = platelet-rich plasma; SD = standard deviation. Methods A and B are described in the text.

βTG levels. In the 5 nonischemic patients in whom circulating platelet aggregates were measured, a decreased ratio reflected an increased amount of circulating aggregates. In patients with 1- or 2-vessel disease, ADP-induced aggregation increased in 18 of 22 patients, compared with 9 of 27 with 3-vessel disease ($p < 0.001$) (Fig. 1). Platelet aggregation increased in most patients with a positive MLE (Fig. 2), while in patients with a negative MLE, it decreased in some and increased in some.

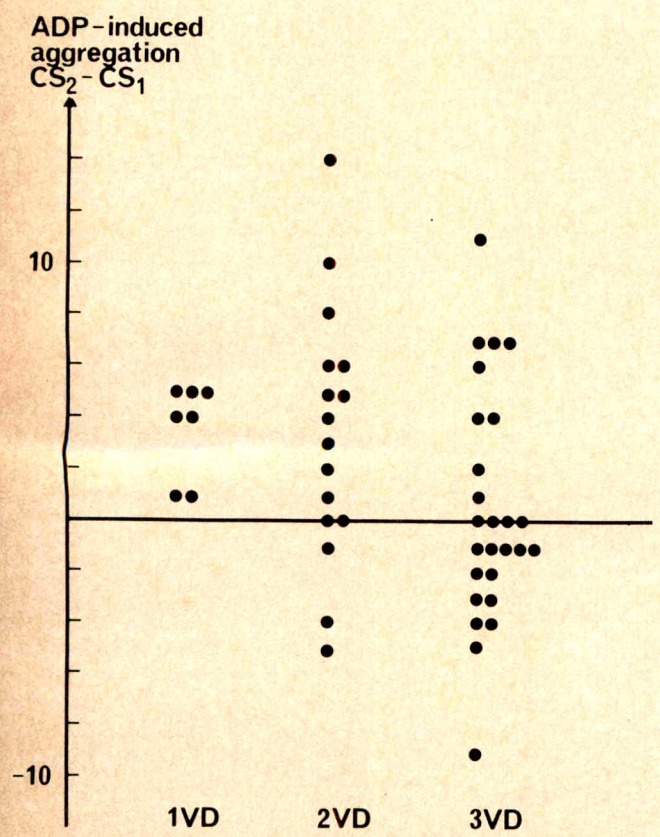

FIGURE 2. Relation between 1-, 2- or 3-vessel disease (1VD, 2VD, 3VD) and the difference between adenosine diphosphate–induced aggregation in coronary sinus blood at rest (CS_1) and during pacing (CS_2).

Platelet function was similar during 2 consecutive pacing episodes separated by a 45-minute interval. Thus, for ADP-induced aggregation, $r = 0.83$ ($p < 0.001$) and CV = 26.5, and for collagen-induced aggregation, $r = 0.86$ ($p < 0.001$) and CV = 29.7. The retention response showed greater variability: Method A, $r = 0.26$ ($p > 0.10$) and CV = 48.8; Method B, $r = 0.52$ ($p < 0.01$) and CV = 40.9. For plasma βTG levels, $r = 0.71$ ($p < 0.01$) and CV = 27.0. For total platelet counts in native blood, $r = 0.94$ ($p < 0.001$) and CV = 11.9, and for platelet counts in PRP, $r = 0.92$ ($p < 0.001$).

Discussion

The clinical recognition of myocardial ischemia may be difficult. Angina can occur without evidence of insufficient myocardial blood supply[17] and transient ST-segment changes may indicate ischemia in the absence of chest pain.[18] Lactate levels were measured in the present study not only to detect ischemia, but also to verify that the coronary sinus blood drained ischemic myocardium. The finding of net lactate production in only half of the patients with pacing-induced chest pain demonstrates that ST-segment changes or pain alone did not ensure that blood would be collected from ischemic myocardium. Pacing-induced myocardial ischemia as measured with lactate metabolism or ST-segment depressions has been reported to be highly reproducible.[19]

Platelet function was reduced in blood that had passed the arteriosclerotic coronary vessels at rest, in agreement with previous reports.[6,8,11] Possible mechanisms may be refractoriness after mild platelet stimulation or the effect of platelet inhibitors released in the coronary vessels.

Surprisingly, platelets were, on the average, unaffected in coronary sinus blood during pacing in the ischemic patients. In agreement with these results, others[20] reported that patients with an ischemic lactate response did not increase the coronary sinus plasma levels of platelet factor 4 during pacing. In another study,[7] platelet aggregation was reduced in coronary sinus blood during pacing in patients with net lactate production. The finding of enhanced aggregation during

pacing in another study[6] is difficult to interpret because ischemia was not biochemically verified.

Most patients with 3-vessel disease developed a net lactate production. In these patients, the mean platelet aggregation was unchanged during pacing, while, on the average, the aggregation increased in patients with 1- and 2-vessel disease owing to a high proportion of nonischemic patients in whom platelets were almost uniformly activated. This activation is in agreement with the results of a study in healthy subjects with a nonischemic lactate response to pacing.[7] In another study[6] in which lactate measurements were not included, in patients with chest pain but normal coronary angiograms, platelet aggregation was unchanged in coronary sinus blood during pacing.

The present results suggest that factors other than ischemia induce platelet activation in the coronary circulation. A lack of activation in ischemic zones may be salutary and may explain why anginal episodes do not progress into irreversible myocardial damage more often. The mechanism of activation in nonischemic regions is not apparent, but reports of more pronounced catecholamine release from nonischemic than ischemic myocardium during stress and a good correlation between platelet activation and catecholamine release fit with the present results.[21,22] However, platelets are modulated by a number of factors. The proaggregatory thromboxane A2 as well as antiaggregatory prostacyclin are both released during stress.[23] The net effect of these and other mediators of platelet function is difficult to predict, and emphasizes the advantage of studying measurements of platelet responsiveness itself.

The present study reveals that platelets are affected differently in ischemic and nonischemic myocardium, and since coronary sinus blood is a mixture of blood from these regions, the degree of platelet activation during pacing probably depends upon whether the dominating proportion of the coronary sinus blood is sampled from ischemic or from nonischemic zones. The changes induced during pacing were moderate, but could be detected, because the influence of the sampling procedure on the platelets is mild.[11]

Animal studies and autopsy findings suggesting that platelet aggregation may cause plugging of coronary vessels, resulting in myocardial necrosis,[4,5,24] have been supported by the demonstration of platelet activation in nonischemic myocardium during tachycardia stress. Thus, an improved prognosis in coronary artery disease may be achieved not only by antianginal regimens that reduce myocardial ischemia, but also by specific platelet inhibition, which may be beneficial to patients with arteriosclerotic heart disease.

Clinical Data Versus Noninvasive Testing as an Estimate of Coronary Status

SAMUEL H. BROOKS, ScD, JOHN W. ALLEN, MD, W. ALLAN EDMISTON, MD, FRANCIS Y. K. LAU, MD, and DAVID H. BLANKENHORN, MD

The step from coronary angiography to surgery is taken primarily on the basis of the ejection fraction (EF) and number of diseased vessels (NV), taken jointly as coronary status (CS). This study reviewed (1) how well EF, NV and CS are estimated from clinical data, (2) how much improvement is gained by adding noninvasive data, (3) how good this model is when applied to a larger cohort and (4) whether the decision to angiography can be made on the basis of CS estimated from clinical data alone. A quantitative definition of CS was established as a principal component of EF and NV. Estimates of EF, NV and CS were made from clinical data of 60 patients. Correlations with the actual values were EF 87%, NV 93% and CS 93%. When noninvasive data were added to this model, the correlations increased to EF 95%, NV 99% and CS 98%. When the clinical data model was applied to 169 patients, the correlations decreased to EF 77%, NV 71% and CS 74%.

CS estimated from clinical data alone was set up as a test for angiography for 169 patients. This test had a sensitivity of 98% and a specificity of 63%, demonstrating the feasibility of using clinical data alone in deciding angiography.

(Am J Cardiol 1983;52:470–476)

Angiography has emerged as the most definitive procedure for assessing coronary disease. It is a critical step on the path of clinical data, noninvasive testing, angiography and surgery. In this report, we discuss the decision to perform angiography. This decision, however, is overshadowed by the decision to perform surgery. Results of angiography can be summarized in terms of ejection fraction (EF) and number of diseased vessels (NV). These variables are jointly evaluated, usually subjectively, in terms of a single decision criterion, which we call coronary status (CS). To deal with these concepts quantitatively, we formalize a definition for CS (Fig. 1). A low CS indicates surgery, a high value no surgery, and an intermediate value requires that other factors be brought into consideration.

Investigators have set up EF and NV as standards for evaluating noninvasive tests. Several studies have related these test results, such as ST-segment depression, with coronary anatomy.[1–3] Further refinements have combined test results with clinical data to make angiographic predictions.[3–8] Using test results in addition to clinical data alone increases the costs and decreases the number of patients to whom these methods can be applied; for example, patients with unstable angina who cannot exercise.

For this study, we reviewed the charts of a limited number of patients who had angiography. The questions explored were (1) How well are EF, NV and CS estimated from clinical data? (2) How much improvement is gained by adding noninvasive data? (3) How good is this model when applied to a larger cohort? (4) Can the decision to perform angiography be made on the basis of CS estimated from clinical data alone?

Methods

Two groups of patients were studied. Group I included 60 patients who had clinical data and noninvasive tests. Group II included 109 patients who had clinical data alone. The Group I study evaluated clinical data and noninvasive tests as predictors of EF, NV and CS. The Group II study further defined the predictive ability of the clinical data derived from the Group I patients in a more heterogeneous patient group. The period of study was 1975 to 1978.

The patients underwent cardiac catheterization either to diagnose presence or quantitate the degree of disease. Each patient was suspected of having coronary artery disease or congestive heart failure unrelated to valvular disease. Patients were excluded if they had obvious valvular disease or a contraindication to any of the studies.

Data: Every patient had a history and physical examination, electrocardiogram, and determination of EF, NV and CS. The Group I patients also had a chest roentgenogram, exercise stress test and ultrasound analysis. Table I defines the variables and how they were coded. Unspecified codes were absent 0, present 1.

Histories were obtained from chart review. Angina pectoris was diagnosed from retrosternal chest pain produced by effort and relieved by nitrates or rest. Hypertension was diagnosed from a history of receiving medication for hypertension or a resting blood pressure over 140/90 mm Hg. Diabetes was diagnosed if the patient so indicated when asked. Congestive heart failure was diagnosed if the patient complained of dyspnea or orthopnea or had dependent rales.

A standard 12-lead electrocardiogram was evaluated using New York Heart Association criteria.[9] One modification was the acceptance of ≥30 ms Q-wave duration in lead aVF as an indication of inferior infarction.

A standard posteroanterior view of the chest was evaluated. Blood redistribution to the upper lobes was estimated using the technique of Turner et al.[10] Heart size estimates from the chest film were derived from a table based on height and weight and expressed as a percentage of predicted normal.[11]

Each patient performed a standard treadmill stress test, using the Bruce protocol and 12 leads. The entire test was scanned for evaluation of ST-segment depression (start of exercise to 5-minute recovery). If ST-segment depression was present initially, a change in the depth of the ST segment was recorded. The ST segment was evaluated 80 ms after the J point. Blood pressure and heart rate were measured by sphygmomanometer and electrocardiogram, respectively.

M-mode echocardiograms were performed using a Unirod-D echocardiogram interfaced with a Honeywell fiberoptic recorder. A single view of the ventricle recorded in the standard transducer position was used for measurement. The measurements presented were determined using previously published guidelines.[12]

EF and NV were combined to provide a more global measure of the CS. This was done using BMDP4M factor analysis,[13] which, in essence, transforms the 2 measures into stan-

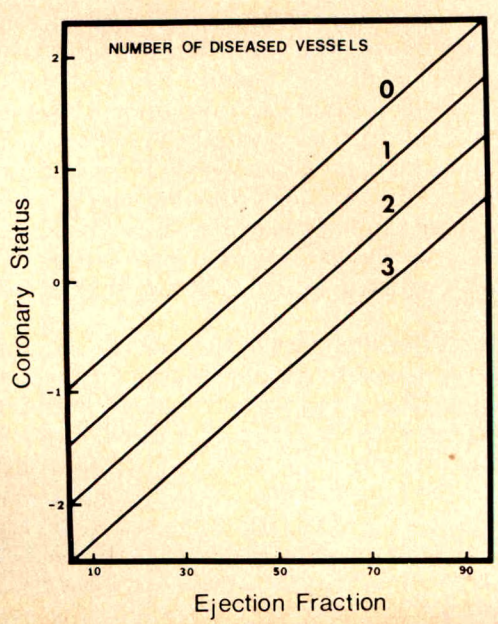

FIGURE 1. Coronary status as a function of ejection fraction and number of diseased vessels.

TABLE I Study Variables, Specification, and Coding (unspecified codes are no 0, yes 1)

I. History and physical
- 1 Age at diagnosis (years)
- 2 Sex (male 1 female 2)
- 3 Caucasian
- 4 Months since myocardial infarction (−12 if none)
- 5 Number of myocardial infarctions
- 6 Family history of heart attacks
- 7 Typical chest pain
- 8 Nontypical chest pain
- 9 Resting chest pain typical of coronary insufficiency
- 10 History of smoking
- 11 History of diabetes
- 12 Treatment with digitalis
- 13 Treatment with diuretic
- 14 Hypertension requiring treatment
- 15 Exertional dyspnea, orthopnea or paroxysmal dyspnea
- 16 History of edema
- 17 Height (in)
- 18 Ponderal index (lb/(height × height)
- 19 Systolic blood pressure
- 20 Diastolic blood pressure
- 21 Heart rate (beats/min)
- 22 Rales or wheezes
- 23 Apical systolic murmur
- 24 Harsh basilar systolic murmur
- 25 S_3
- 26 S_4
- 27 Pretibial edema
- 28 Distended neck veins

II. Electrocardiographic variables
- 29 Anterior infarction
- 30 Lateral infarction
- 31 Posterior infarction
- 32 Inferior infarction
- 33 Anterior ischemia
- 34 Lateral ischemia
- 35 Inferior ischemia
- 36 Left ventricular hypertrophy
- 37 Left atrial enlargement
- 38 Right atrial enlargement
- 39 Conduction defect
- 40 Premature atrial beat
- 41 Premature ventricular beat
- 42 Atrial fibrillation

III. Roentgenographic variables
- 43 Transverse cardiac diameter (percent normal: 90–110)
- 44 Left ventricular enlargement (none = 1,2,3,4 = marked)
- 45 Right ventricular enlargement (none = 1,2,3,4 = marked)
- 46 Other chamber enlargement (none = 1,2,3,4 = marked)
- 47 Pulmonary vascular congestion (none = 1,2,3,4 = marked)
- 48 Chronic obstructive airway disease

IV. Exercise stress test variables
- 49 Angina pain present
- 50 Maximal heart rate
- 51 Double product at maximal exercise: (0.01 × systolic blood pressure × heart rate)
- 52 Stage ST-segment depression of ≥1 mm
  1. 1.7 mph, 10% grade
  2. 2.5 mph, 12% grade
  3. 3.4 mph, 14% grade
  4. 4.2 mph, 16% grade
  5. No ST-segment change
- 53 Stage patient has chest pain or fatigue (as above)
- 54 Decrease in blood pressure of ≥10 mm Hg
- 55 ST-segment depression at maximal exercise (mm)

V. Echocardiographic measurements
- 56 Left ventricular internal dimension in diastole (normal 3.5–5.7)
- 57 Left ventricular internal dimension in systole
- 58 Fiber shortening (LVIDd-LVIDs)/LVIDd (normal 0.24–0.46)
- 59 EPSS (mm) from E point of mitral valve to septal surface
- 60 Posterior wall excursion (normal 0.9–1.4)
- 61 Septal excursion (normal 0.3–0.8)
- 62 Myocardial scar present
- 63 B notch in mitral valve

VI. Angiographic measures
- 64. Number of diseased vessels
- 65 Ejection fraction
- 66 Coronary status (combined number of diseased vessels and ejection fraction)

LVIDd = diastolic left ventricular internal diameter; LVIDs = systolic left ventricular internal diameter; EPSS = E point to septal surface.

TABLE II Variables Significantly Correlated with Number of Diseased Vessels or Ejection Fraction—Variable Means, Standard Deviations, and Correlations with Angiographic Variables

dard scores, which were averaged. The resulting CS value has a mean of 0.0 and a standard deviation of 1.0. Figure 1 shows how CS is derived from any combination of EF and NV. Positive values of CS are a consequence of a high EF and low NV. In general, a CS >0 translates into a no-surgery decision, a CS < −1 implies surgery, and −1 < CS < 0 is equivocal. As a basis for comparison, we adopt the convention that a CS > −0.5 is a decision for no surgery and a CS < −0.5 is a decision for surgery.

Analysis: Statistical analysis was done using biomedical computer program BMDP2R stepwise regression.[13] For each variable, the mean, standard deviation and correlations with the angiographic findings were calculated. For the Group I patients, variables were found that were significantly predictive when taken together. This was done in a sequential manner: (1) examining the history and physical and electrocardiographic variables, (2) augmenting these by the chest roentgenographic variables, (3) augmenting these by the exercise stress test variables and (4) further augmenting by the echocardiographic variables. Predictive ability was measured in terms of the standard error of estimate, which is the standard deviation of the predicted from the actual value. To explore the generality of the methods, all 169 patients were treated as a single group to develop predictive models based on the history and physical and electrocardiographic variables.

Results

Table II is a summary of the data from the 2 groups for variables significantly correlated with the angiographic findings. Group II was older, but had an average higher EF. The older patients had a higher NV. Males had fewer NV and better CS. The time since last myocardial infarction and the number of previous infarctions were adverse (i.e., had a worse CS). Angina was associated with a greater NV but higher EF. The use of digitalis was related to a lower EF. Exertional dyspnea appeared in conjunction with a lower EF but a lower NV. Exertional dyspnea appeared in conjunction with a lower EF but a lower NV. A higher systolic blood pressure was found with a higher EF. The presence of distended neck veins or an S_3 suggested a lower EF. Of the electrocardiographic variables, only inferior infarction was strongly indicative of NV and, thereby, a diminished CS. Anterior infarction and left or right atrial enlargement implied a lower EF. A higher exercise maximal heart rate was related to fewer NV. Four of the echocardiographic measurements had a high correlation with lower EF.

Table III is a summary of the ability of sets of noninvasive variables to predict the angiographic measurements. This is done in terms of how well the predicted agrees with the actual, expressed as correlation and standard error of estimate. For example, the stepwise regression program found 12 variables from the 42 history, physical and electrocardiogram variables (sets I and II) that were jointly predictive of the EF. The (multiple) correlation of the prediction based on these 12 variables with the actual EF was 0.87. The standard error of estimate was 10.5%. This implies that if these

	Specificity	63%	...	...	...

* Patients correctly classified by noninvasive estimate of CS.

12 variables were used to predict an EF, for example, 65%, then about two-thirds of the time an angiogram would yield an actual value from 65 − 10.5 to 65 + 10.5, and 95% of the time from 65 − 21 to 65 + 21. Figure 2 displays how well the predicted EF agrees with the actual EF. In general, increasing the number of test sets increased the correlation and decreased the standard error of the estimate. An exception to this was for NV, since adding the echocardiographic measurements was not recognized as providing additional information.

The above analysis was based on only the 60 Group I patients, but with a large number of variables. As a result, the method was too optimistic. Using clinical variables alone, this model was applied to all 169 patients from both groups. Table III shows a considerable reduction in correlation and an increase in standard error of estimate.

The upper part of Table IV shows the performance of the estimated CS which, when <0, is taken as indicating angiography. At this cutpoint, there were 82 + 49 (78%) patients correctly assigned, with a sensitivity of 89% (95% confidence limits 78 to 96%) and a specificity of 72% (95% confidence limits 63 to 80%). Estimated CS, when high or low, is quite definitive, but reaches its nadir of agreement near −0.5.

Sensitivity and specificity can be adjusted as a function of the cutpoint. In this case, a higher sensitivity was found. The lower part of Table IV shows the performance of the estimated CS which, when <0.12, is taken as indicating angiography. At this cutpoint, there were 72 + 54 (75%) patients correctly assigned, with a sensitivity of 98% (95% confidence limits 90 to 100%) and a specificity of 63% (95% confidence limits 53 to 73%).

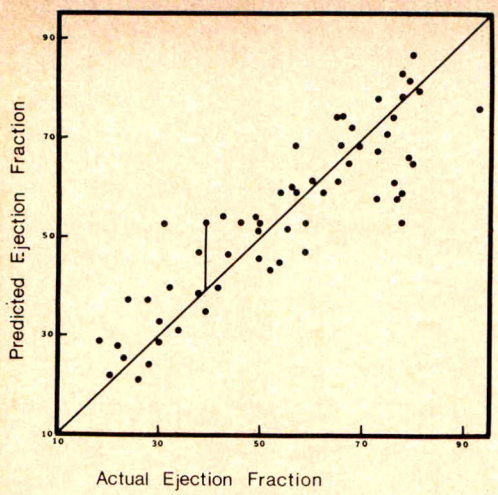

FIGURE 2. Actual and predicted ejection fraction based on significant history, physical, and electrocardiographic variables. The vertical line shows the deviation of the predicted from the actual for 1 patient.

TABLE V Example of Estimating Coronary Status From Clinical Data of a Patient

Clinical Variable	Patient Code	Coefficient
(constant)		−0.905
1 Age	45	−0.011
2 Sex	1	0.588
5 Number of myocardial infarctions	3	−0.198
7 Angina	0	−0.208
10 Smoker	1	−0.340
11 Diabetic	0	−0.623
12 Digitalis	1	−0.233
16 Edema	0	0.714
18 Ponderal index*	0.0265	19.334
19 Systolic blood pressure	135	0.008
25 S_3	1	−0.786
29 Anterior infarct	0	−0.755
32 Inferior infarct	1	−0.487
38 Right atrial enlargement	0	−0.697
41 Premature ventricular beat	0	−0.427

Estimated coronary status = −1.66.
* Weight/(height × height) = 145/(74 × 74).

Table V is an example of how the estimated CS was calculated. The variables involved, a patient's values and the regression coefficients are shown. Estimated CS = −1.66 was computed by multiplying each value by the corresponding coefficient, summing up and adding the constant. The actual CS was close to this, since actual EF = 30% and actual NV = 3.

Discussion

This review was a feasibility study of a small number of highly selected patients done by retrospective chart review. Thus, the generality of the results is limited. Patients with findings of valvular disease or congenital abnormalities were excluded. Those included had chest pain suggestive of angina pectoris or congestive heart failure unrelated to valvular disease. In Table V, some of the coefficients are more of a reflection of our particular sample, rather than representing a more general population. Edema, ponderal index and systolic blood pressure were positively related to CS; the higher they were, the better the CS. For example, the anomalous edema coefficient may have been a consequence of having several patients with congestive cardiomyopathy. Their high edema measurement would be correlated with a low NV despite a low EF, so their CS would be higher than that in patients with low edema measurement. Other variables of the 42 candidates may not have been included if they did not contribute added and significant information. The reader is not encouraged to use this model to make patient decisions for a different population.

Angiograms had been done to evaluate the patients as candidates for aortocoronary bypass graft surgery or aneurysm resection. Recent reviews[14] evaluating patients for bypass surgery have used symptoms and angiographic findings as the basis for the surgical decision. Of interest here are ventricular function, location of diseased vessels and NV. Surgery was not recommended in patients with severe nonreversible ventricular dysfunction. Patients with symptoms, 3-vessel disease and moderate impairment of ventricular function were regarded as good surgical candidates. The clinician was required to evaluate symptoms as well as coronary anatomy and ventricular function.

Currently the physician starts with clinical variables—history, physical examination and electrocardiogram. At this point, he or she could decide on angiography or opt for more information from noninvasive tests. Those most extensively studied have been chest film and exercise, usually including ST-segment change during a treadmill stress test. Echocardiography and radionuclide procedures have been recently introduced. The data used in this study were gathered before the radionuclide procedures were available to us, so none were reported here. Use of noninvasive tests as a predictor of coronary disease has evolved from case reports to much more extensive analysis in the past decade. The ultimate end points have been mortality and morbidity or, more positively, the length and quality of life. As angiography progressed, noninvasive testing was used to predict the angiographic results and then combined with them to predict mortality and morbidity. Inevitably, many noninvasive variables were combined into a single index as a basis for prediction,[15–17] as we have done here in defining CS.

Statistical analysis has progressed in concert with the type of data gathered. Contingency tables and chi-square tests were used to describe risk factors and end points, most often grouped as presence or absence.[18–20] For survival data, life tables and Cox analysis were used.[8,15–17,21,22] Discriminant analysis was used to find how to combine the noninvasive measures into a single index predictive of the presence of disease.[2,23] These measures can be either continuous, as age, or discrete, as sex. Disease is ordinarily taken as a dichotomy, that is, absent, or present if there is a coronary stenosis of ≥50% in at least 1 vessel. Stepwise discriminant analysis is a fairly efficient method of selecting the set of most promising variables and discarding those that do not add substantive and independent information.[15,24]

Concepts of test evaluation common in clinical laboratory practice[25] can be used to evaluate noninvasive testing. Sensitivity is the percentage of test results that are above a disease threshold, that is, positive, from a population of whom all are diseased. More explicitly, this can be called technical sensitivity. Specificity is the percentage of test results that are below a disease threshold, that is, negative, from a population of whom none are diseased. More explicitly, this can be called technical specificity. Using 0.12 as the cutpoint in our estimated CS test, these were 98% and 63%, respectively. Diagnostic sensitivity is the percentage of patients who indeed have the disease from a population of whom all had a positive test result. This is also often called the predictive accuracy.[26] Diagnostic specificity is the percentage of patients who indeed do not have the disease from a population of whom all had a negative test result. In the same estimated CS test, these were 99% and 56%, respectively.

Technical sensitivity and technical specificity are properties of the test. On the other hand, diagnostic sensitivity and diagnostic specificity are a consequence not only of the test, but also of the prevalence of the disease in the presenting population.[4] The calculus of these relationships are well known.[4] Receiver-operator characteristic curves are used to express the tradeoffs between diagnostic sensitivity and diagnostic specificity for a given disease prevalence.[6] The cost-effectiveness of test combinations in these terms and the application of information theory is of considerable interest.[5,6] These concepts have been used to show the value of a testing procedure. For the most part, they are not used to quantify the performance of the test when applied to an individual patient. The likelihood of the patient having the disease is, of course, dependent on the test result. The uncertainty decreases toward the more extreme values of CS (Table IV).

The decision to operate is based not only on the knowledge of coronary anatomy, but also on the evaluation of ventricular function. At the bedside, the clinician can frequently detect abnormal heart sounds or evidence of cardiac enlargement. Bruce[27] showed that cardiomegaly plus markedly impaired functional capacity on the treadmill or reduced blood pressure response to exercise can both help to identify severe ventricular dysfunction. These results were derived from patients with established ventricular disease; not included were patients for whom the clinician was unsure of this diagnosis.

Treadmill exercise testing and echocardiographic measurement and radionuclide studies have shown good correlations with angiographic results, although appreciable scatter is present. A more comprehensive combination of these with more conventional clinical variables still must be done.[3,28]

The most promising approach will be not only the incorporation of these more "exotic" tests, but also the sequential use of many variables. These should be selected on the basis of balancing their cost with their incremental information. A variable easy to obtain, such as those in a history, should be included. An expensive test should be included if it provides an appreciable amount of additional information. Such choices may be implemented using decision theory.[29]

When data are gathered, they should be in continuous form to the extent feasible. For example, ST-segment depression should not be categorized as greater than a threshold or not; the amount should be recorded.[5] It is simplistic to dichotomize variables as normal, abnormal or disease–no disease. In this report we have fallen into this convention. However, it may be essential to dichotomize if, for example, a decision must be made for angiography or surgery.

The findings in this report must be viewed as demonstrating feasibility, rather than providing quantitative answers. Angiographic findings of EF, NV and CS can be estimated from clinical data with high significance. Noninvasive data provide even better estimates. We have not quantitated this improvement as well as is needed to support a cost/benefit analysis. There were appreciable decreases in correlations when the models developed for the small group were applied to the larger and more heterogeneous group. However, they were still quite significant. Clinical data alone were adequate as a basis for deciding angiography. Estimated CS can be viewed in the same way as a laboratory test. In this study, it had a high sensitivity and specificity.

More work must be done to validate these findings, to quantify the models, and to make them generally applicable. Improvement can be made with a wider cohort of patients at many institutions, introduction of more recent noninvasive tests (for example, radionuclide studies) and refinement of the statistical model. The results of others as well as our own are so promising that a more extensive effort should be made to provide the clinician with such a service.

Free Your Angina Patient...
from some constraints of
beta-blocker therapy

Calan® TABLETS 80 mg and 120 mg
(verapamil HCl)

A Freer Life-style For Your Angina Patients

Unsurpassed by propranolol in the treatment of angina

- The efficacy of Calan was unsurpassed by that of propranolol in well-controlled comparative studies involving patients with chronic stable angina.[1-4]
- Calan is very effective in unstable[5] and variant angina,[6] where spasm factors may preclude the use of propranolol.[7]

Low incidence of unwanted effects

- Serious adverse reactions are rare with Calan at recommended doses; the single most common unwanted effect is constipation (6.3%). The therapy continuation rate was 94.5% in clinical studies.[8]
- Unlike beta-blockers, Calan rarely causes extreme fatigue or mental depression.

Benefits even for patients who can't take propranolol

- Calan, unlike propranolol, can be used without added caution in angina patients who also have asthma, chronic obstructive pulmonary disease (COPD), or diabetes.

The only non-nitrate indicated for initial therapy for all types of angina

Calan®
(verapamil HCl)
TABLETS
80 mg and 120 mg

A Freer Life-style For Your Angina Patients

▪ Efficacy unsurpassed by propranolol

Calan is effective and, unlike propranolol, is indicated as initial therapy both for stable effort angina and for vasospastic angina.

▪ Therapeutic considerations similar to propranolol

Calan and propranolol have similar cardiovascular contraindications and many of the same cardiovascular adverse reactions (e.g., hypotension, reduction of myocardial contractility, and intensification of AV block).[8,9]

▪ An easy-to-titrate dosage schedule

Initial dosage: 80 mg t.i.d.

Titrate to optimal response:
usually 120 mg t.i.d. or q.i.d.

Calan® (verapamil HCl) TABLETS
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzyme levels monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, and spotty menstruation. Overall continuation rate was 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Role of a Catheter Lead System for Transvenous Countershock and Pacing During Electrophysiologic Tests: An Assessment of the Usefulness of Catheter Shocks for Terminating Ventricular Tachyarrhythmias

LAWRENCE E. WASPE, MD, SOO G. KIM, MD, JEFFREY A. MATOS, MD, and JOHN D. FISHER, MD

The practicality and safety of using a single catheter system for transvenous countershock, programmed stimulation and ventricular pacing during electrophysiologic tests were evaluated in 13 patients with inducible sustained ventricular tachycardia (VT) or ventricular fibrillation (VF). The efficacy and patient toleration of transvenous countershock were compared with other methods of arrhythmia termination. The same lead was used for programmed stimulation at the right ventricular apex and for VT termination by pacing methods during serial testing (20 ± 15 days [mean ± standard deviation]). Synchronized countershock using energies that patients found tolerable (0.01 to 5 J) terminated 31 of 50 episodes (62%) of induced VT. Episodes of VT cardioverted with these low energies were distinguished from other episodes by a longer cycle length (352 ± 62 ms versus 297 ± 50 ms, $p < 0.004$). Among paired episodes of VT matched for patient, date of induction, morphologic characteristics, cycle length and drugs administered, pacing methods (single extrastimuli and bursts of rapid pacing) were just as effective as low-energy countershock for VT termination (25 of 25 versus 21 of 25, difference not significant). Transvenous countershock was uniformly effective for termination of ventricular flutter and VF when sufficient energy was used (range 5 to 30 J, mean 20.4 ± 7.7). This required interfacing leads to a defibrillation unit. VT acceleration occurred during 7 of 50 synchronized low-energy cardioversion attempts (14%). There was no evidence of myocardial injury as a result of shocks as high as 30 J, but patients required increasing sedation when energy exceeded 0.5 J.

Thus, a single catheter system can be used for programmed stimulation, ventricular pacing and countershock during electrophysiologic tests. Low-energy countershock (0.01 to 5 J) is no more effective than pacing methods for VT termination and is tolerated less well. The most practical use of this catheter system, including any implantable unit, may be for slightly higher energy (5 to 30 J) countershock termination of repeated episodes of very rapid VT or VF, in which pacing techniques are ineffective. This method may be safer and less traumatic than conventional transthoracic countershock.

(Am J Cardiol 1983;52:477–484)

A variety of techniques for terminating ventricular tachyarrhythmias are available or under investigation.[1–16] Pacing techniques are well-tolerated by patients, but are frequently ineffective for rapid ventricular tachycardia (VT) and useless for ventricular fibrillation (VF).[1–7] External countershock is effective for the termination of ventricular tachyarrhythmias, but is traumatic and may result in skin burns or injury to the myocardium.[17,18] An alternative method of tachycardia termination that is more reliable than pacing, less traumatic than conventional countershock, and suitable for implantation would clearly be desirable.

For more than a decade, the feasibility of using intracardiac shocks to terminate ventricular tachyarrhythmias has been known.[12–14] This has resulted in the development of an effective automatic implantable defibrillator that delivers 25-Joule (J) shocks.[15,16] Re-

cently, lower energies delivered through an intravascular electrode catheter have been used safely in dogs and patients to terminate spontaneous and laboratory-induced VT.[8–11]

In the present study we assessed the role of an intravascular electrode catheter in the electrophysiology laboratory. We evaluated the safety, efficacy and practicality of using a catheter lead system for low-energy countershock, programmed ventricular stimulation and pacing termination of VT in patients with inducible sustained ventricular tachyarrhythmias. In addition, we evaluated patient tolerance of low-energy transvenous countershock and determined the comparative effectiveness of this method and pacing techniques for terminating episodes of induced VT with matched characteristics.

Methods

Patients (Table I): Patients were referred to the Arrhythmia Service at the Montefiore Medical Center for electrophysiologic evaluation of recurrent symptomatic ventricular tachyarrhythmias or syncope of undetermined origin. There were 12 men and 1 woman, aged 48 to 72 years (mean 57). Six patients had a history of recurrent sustained VT. Four patients had had cardiac arrests, and VF was documented at the time of resuscitation. One patient had recurrent episodes of nonsustained VT and 2 patients had episodes of syncope without a documented cause. Patients had experienced 1 to 10 occurrences of clinical arrhythmias before presentation. Ten patients had required conventional transthoracic countershock on 1 to 4 occasions.

All patients had coronary heart disease and 11 had had 1 or more remote myocardial infarctions. A left ventricular aneurysm was present in 5 patients. Cardiac surgery had been performed in 4 patients before referral for arrhythmia evaluation. Three patients had undergone coronary artery bypass grafting, and 1 patient had coronary artery bypass grafting and aneurysmectomy for symptoms of heart failure. Heart size was normal in 4 patients, whereas 9 patients had evidence of cardiomegaly on the basis of chest radiographs that demonstrated cardiothoracic ratios >0.50. Left ventricular ejection fraction determined by angiographic catheterization or gated radionuclide ventriculography ranged from 27 to 55% (mean 40 ± 9).

Approval to use a transvenously positioned catheter for internal cardioversion was obtained from the institutional review board of the Medical Center before recruitment of patients for this study. All patients gave written informed consent.

Catheter and system for transvenous countershock: The temporary electrode catheter used for internal countershock is a No. 9.5 Fr tripolar polyurethane insulated lead (Medtronic model 6880) (Fig. 1). The lead has 4 large, stain-

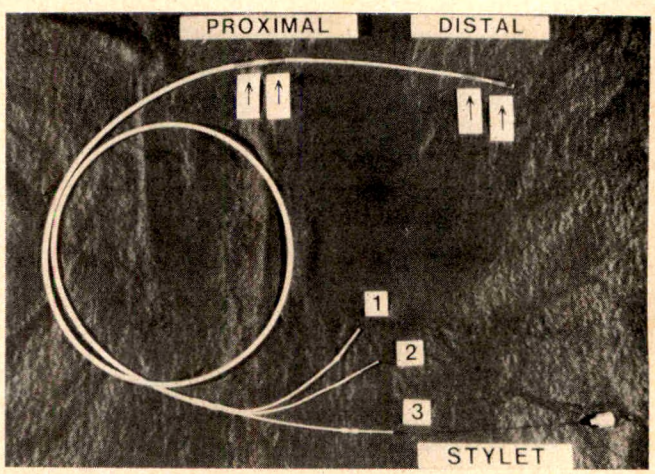

FIGURE 1. Catheter lead. **Arrows** point to stainless-steel electrodes. The distal pair are positioned at the right ventricular apex; the proximal pair are electrically common and lie in the right atrium or superior vena cava. 1, 2 and 3 refer to connector pins to the distal (ventricular) electrodes and the proximal common electrode. A stylet can be inserted into the catheter through connector pin 3 to aid in lead positioning. See text.

less-steel electrodes, each with a surface area of 1.25 cm^2. The distal pair of electrodes are located at the catheter tip and are separated by a 5-mm distance. The other pair of electrodes are separated by 5 mm, but form a single pole, and are located 100 mm proximal to the distal pair. Each electrode is connected to a separate conductor coil that terminates on 1 of 3 connector pins at the proximal end of the catheter. Catheter electrode spacing is designed so that positioning the distal pair in the right ventricular apex places the proximal common electrodes in the high right atrium or superior vena cava. The distal (ventricular) electrodes are used for electrogram sensing and can be used for bipolar ventricular pacing. During cardioversion or defibrillation, the distal electrodes are made electrically common, and form the cathode. The proximal common electrodes become the anode.

The catheter was inserted into the left subclavian vein using a percutaneous introducer technique and advanced under fluoroscopic guidance to the right ventricular apex. A stylet could be inserted into the lumen of the innermost conductor coil through 1 of the connector pins to stiffen the catheter sufficiently for positioning in the heart. Lead stability was verified by a chest radiograph within 24 hours of insertion and confirmed on subsequent days by fluoroscopy in the catheterization laboratory.

The catheter was connected to a battery-powered cardioverting device (Medtronic model 2342), which delivered a truncated exponential wave form, 5.5 ms in duration, at 10 energy levels ranging from 0.01 to 5.0 J. This cardioverting unit functioned in either a synchronous or asynchronous mode. When operating synchronously, an output pulse occurred at the first sensed electrical event after the discharge control was pressed. Sensing was performed by an amplifier in the unit that had a refractory period of 220 ms and a sensitivity continuously variable from 0.5 to 20 mV. The timing of synchronous pulses was verified by a sense marker signal (6 to 9 V, 5 ms in duration) before countershocks. When the asynchronous mode was selected, pressure on the discharge control produced an immediate output.

By means of terminals and switchbox contructed in cooperation with the Biomedical Engineering Department of the Medical Center, the cardioverting lead was connected simultaneously to a standard defibrillation unit (Physio-Control Lifepak 911). With this design, synchronous or asynchronous shocks could be delivered at higher energy levels (10 to 30 J) when needed. A Devices/Digitimer 4279 programmable stimulator and a Medtronic 5320 pulse generator were interfaced to the catheter's distal electrode pair through terminals on the cardioverting unit, permitting use of the cardioverting lead for programmed stimulation and ventricular pacing.

Study protocol: Patients became candidates for cardioverting lead insertion if sustained VT or VF was reproducibly initiated during a routine initial electrophysiologic study, using standard programmed stimulation techniques.[19] Briefly, initial electrophysiologic studies involved the insertion of 2 multipolar electrode catheters with the use of a percutaneous introducer technique into the subclavian and femoral veins. One catheter was positioned in the right ventricular apex and the other across the tricuspid valve to record the His bundle potential. Pacing was performed by means of a Devices/Digitimer 4279 programmable stimulator using stimuli 1 ms in duration at 4 times diastolic threshold. Ventricular arrhythmias were initiated by scanning diastole with 1, 2 or 3 ventricular extrastimuli during sinus rhythm or ventricular pacing at cycle lengths of 600 to 425 ms. If extrastimuli failed to induce ventricular tachyarrhythmias, bursts of rapid ventricular pacing were tried (10 to 20 beats) at cycle lengths of 500 to 240 ms. No patient in the study required stimulation at other right ventricular sites, isoproterenol infusion or left ventricular stimulation in order to initiate ventricular tachyarrhythmias. The arrhythmias induced reproduced arrhythmia morphologies and symptoms that had been documented clinically.

After induction of sustained VT or VF, the multipolar ventricular catheter was replaced with a cardioverting lead in the electrophysiology laboratory. Most often this replacement was performed the day of the initial electrophysiologic evaluation. Once positioned, the lead was used for programmed stimulation, pacing and transvenous countershock in the course of serial antiarrhythmic drug evaluation.

On initiation of sustained VT, output energies of 0.01, 0.05, 0.10, 0.25, 0.50, 0.75, 1.0, 1.5, 2.0, and 5.0 J were delivered in the synchronous mode in attempts to restore sinus rhythm. Efforts were made to deliver shocks in an incremental fashion until successful conversion to sinus rhythm occurred. However, when VT was not well-tolerated or resulted in hemodynamic instability, the higher energies in this range were initially and subsequently selected in attempts to terminate arrhythmias quickly. To avoid the reported possibilities of VT acceleration or precipitation of VF, transvenous shocks were administered synchronously only when synchronization occurred within the first 80% of the surface QRS interval.[8,9,11] If cardioversion attempts failed with synchronized output energies of $\leq$5 J or ventricular flutter/fibrillation occurred, arrhythmia conversions were attempted through the catheter with asynchronous shocks of 5 J or with synchronous or asynchronous shocks of 10 to 30 J delivered from the interfaced standard defibrillation unit (Physio-Control Lifepak 911). A second defibrillation unit was available (Electronics for Medicine model ISD) in case backup transthoracic shocks were needed. Patients were sedated with 2 to 10 mg of intravenous diazepam if discomfort occurred during incremental attempts at cardioversion.

Cardioverting leads were used in 8 patients who gave informed consent, to compare the efficacy of synchronized transvenous countershock (0.01 to 5 J) with that of pacing techniques for terminating laboratory-induced VT. Pacing methods used to terminate VT included scanning diastole with a single extrastimulus and rapid pacing at cycle lengths of 400 to 220 ms for 5 to 10 seconds. Countershock and pacing methods were alternately used in attempts to terminate paired episodes of VT, which were matched for patient, cycle length, morphologic characteristics, antiarrhythmic drugs administered and day of induction.

During electrophysiologic studies, VT was defined as sustained if it persisted for >15 seconds or required termination in less time because of hemodynamic compromise. Catheter shocks of 0.01 to 5 J, delivered from the cardioverting device, were defined as *low-energy* transvenous countershocks. Shocks of 10 to 30 J, which required use of the interfaced defibrillation unit, were defined as *high-energy* transvenous countershocks. Recordings of ECG leads 1, 2, aVF, and V_1, intracardiac electrograms, and sense marker signals were displayed on the oscilloscope of an Electronics for Medicine physiologic recorder (DR-12 or VR-12) and simultaneously recorded on heat-sensitive paper or on an 8-channel Siemens-Elema Mingograf at paper speeds of 25 to 100 mm/s.

Serum creatine kinase activity was measured in 10 patients 24 hours after studies involving transvenous, but not transthoracic, countershocks, to evaluate the possibility of catheter shock-related myocardial injury. All creatine kinase determinations included an agarose gel electrophoresis assay (Beckman Paragon System) for B-subunit activity (myocardial isoenzyme). The values of total creatine kinase and B-subunit activity were considered elevated if the values exceeded the normal range (10 to 100 IU/liter and 4% of total creatine kinase activity, respectively).

Summary				
VT episodes	31	12	3	4
Range of VT cycle lengths (ms)	(230–470)	(230–370)	(230–310)	(270–3

* Low-energy (0.01 to 5 J) transvenous cardioversion (TVCV) was attempted during all 50 episodes of induced ventricular tachycardia synchronized, low-energy shocks were ineffective, patients became hemodynamically unstable, VT accelerated, or ventricular flutter/fib occurred, termination was achieved by other methods: rapid ventricular pacing (RVP), synchronous (sync) or asynchronous (async) tran shocks of 10 to 30 J, or transthoracic cardioversion (DCCV). See text for details.

VT episodes are organized according to patient and ultimate method of termination. Cycle lengths of the VT episodes in milliseconds are individually or as a range in parentheses.

† VT was accelerated by low-energy TVCV attempts. In 1 instance further low-energy TVCV attempts were successful. In the other, DC necessary.

‡ Catheter lead was not interfaced to a defibrillation unit, which would have permitted high-energy TVCV attempts.

§ Ventricular fibrillation was precipitated during low-energy TVCV attempts.

Statistical methods included the Student *t* test for paired and unpaired data, Fisher's exact test and McNemar's test for correlated proportions where appropriate. The Mann-Whitney nonparametric test was used to compare variables across 2 groups. Associations between 2 continuous variables were assessed using the Spearman rank-order correlation coefficient. Data are expressed as mean ± standard deviation. Results were considered statistically significant at $p < 0.05$.

Results

Lead insertions and programmed stimulation: Uncomplicated catheter insertions were carried out in the electrophysiology laboratory in 13 patients (Table I). Leads remained in stable position for 1 to 45 days (mean 20 ± 15 days). One patient required a total of 3 lead insertions (patient 5) due to interruption c trophysiologic studies by coronary artery bypass s in 1 instance and the occurrence of a catheter-r infection on another occasion, to be described. instances the catheter tip was positioned in the ventricular apex. In general, the proximal ca electrodes were located in the right atrium wh heart was enlarged, and in the superior vena cava the heart was normal in size (Table I, Fig. 2). At of lead insertion, initial pacing thresholds with a pulse duration ranged from 0.5 to 2.5 V (mean 1.2 Despite stable lead positions, thresholds increa as much as 10 V (mean 3.6 ± 3.3) from 1 to 3((mean 9 ± 11) after insertion. Nevertheless, ever was usable for programmed stimulation at the ventricular apex for as long as it remained in a pa Upon removal of the catheters, electrodes and insu materials were structurally intact.

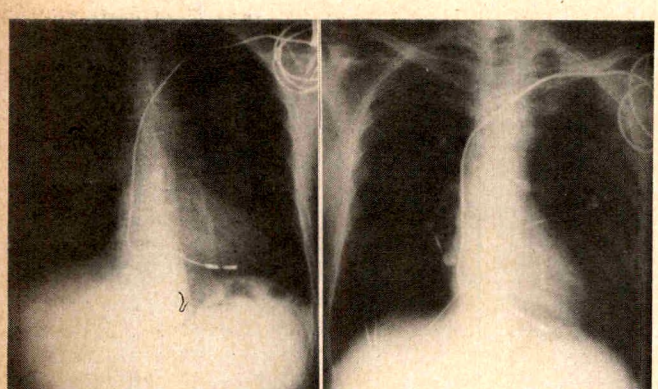

FIGURE 2. Chest radiographs illustrating typical catheter lead placements. **Left,** enlarged heart (Patient 1). The catheter tip is at the right ventricular apex and the proximal common electrode lies in the right atrium. **Right,** normal-sized heart (Patient 4). Positioning the catheter tip at the apex of the right ventricle places the proximal common electrode in the superior vena cava.

Ventricular tachycardia (Table II): During trophysiologic studies, synchronized low-energy to 5 J) transvenous shocks were used in efforts t minate 50 episodes of sustained VT induced in tients (1 to 13 episodes per patient) (Table I). VT lengths ranged from 230 to 470 ms (mean 331 During 47 of 50 episodes, patients were receivin ventional or experimental antiarrhythmic drugs (22 episodes) or in combinations (25 episodes cluding subthreshold attempts, a total of 160 syn nous shocks were delivered, terminating 31 episo induced VT (62%) (Fig. 3).

The remaining 19 episodes of VT required methods of termination. Seven episodes were t nated by *synchronized* transvenous shocks of l energy (10 to 30 J). During these episodes, patie

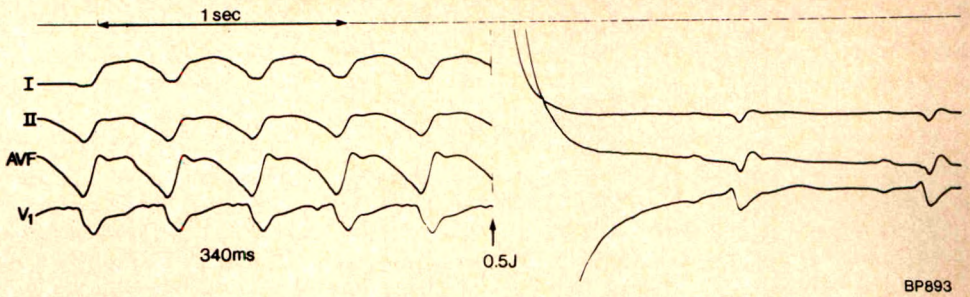

FIGURE 3. Patient 6—termination of ventricular tachycardia (cycle length 340 ms) using low-energy transvenous cardioversion. Scalar leads I, II, aVF and V_1 are displayed. A synchronized catheter shock of 0.5 J (**arrow**) restores sinus rhythm.

ther became hemodynamically unstable and syncopal in the course of unsuccessful low-energy cardioversion attempts or required heavy sedation (≤10 mg of intravenous diazepam) to tolerate intracardiac shocks of ≥10 J. In contrast, patients remained alert or required less sedation when cardioversion was accomplished with energies of 0.01 to 5 J. Five episodes of tachycardia were terminated with *asynchronous* transvenous shocks of 10 to 30 J, when VF occurred during low-energy cardioversion attempts. Four VT episodes were terminated by rapid pacing with the cardioverting lead. Three other episodes of VT were terminated by conventional transthoracic countershock after low-energy attempts failed. These episodes of VT were induced in 2 patients (patients 2 and 3) before catheter leads were routinely interfaced to a source of higher-energy transvenous shocks

Factors correlating with low-energy transvenous countershock efficacy: Episodes of VT terminated by synchronized shocks of 0.01 to 5 J had longer cycle lengths (352 ± 62 versus 297 ± 50 ms, $p < 0.004$ by the Mann-Whitney test) and were characterized by the administration of lower maximum energies during cardioversion attempts (1.40 ± 1.71 versus 3.42 ± 2.14 J, $p < 0.004$ by the Mann-Whitney test). Low-energy countershocks terminated 23 of 42 VT episodes with cycle lengths of 230 to 380 ms (Table II). However, efficacy was uniform (8 episodes) when cycle length exceeded 380 ms. In contrast, the timing of synchronization, expressed as an initial percentage of the surface QRS interval, did not distinguish between tachycardia episodes that were successfully and unsuccessfully treated with low-energy shocks (33 ± 16% versus 42 ± 28%, difference not significant [NS]). Similarly, the success or failure of transvenous cardioversion did not correlate with factors that characterized distal electrode contact with endocardium, such as catheter pacing threshold during programmed stimulation (4.8 ± 3.9 versus 2.4 ± 1.1 V, NS) or endocardial R-wave amplitude recorded during sinus rhythm (5.7 ± 3.1 versus 4.9 ± 1.6 mV, NS) or during VT (7.4 ± 8.5 versus 7.1 ± 0.8 mV, NS). In addition, the efficacy or inefficacy of low-energy countershock was not related to the duration of VT before the initial cardioversion attempt (43 ± 34 versus 34 ± 39 seconds, NS) or to the final attempt (71 ± 56 versus 66 ± 54 seconds, NS).

Among episodes of VT terminated by energies of 0.01 to 5 J, there was no correlation between the energy dose required and VT cycle length, timing of synchronization, pacing threshold, endocardial R-wave amplitude in sinus rhythm or VT, or arrhythmia duration before initial or final shocks. Correlation coefficients ranged from −0.32 to +0.28.

Comparison of ventricular tachycardia termination methods: During electrophysiologic studies, 25 paired episodes of VT were induced in 8 patients to compare the termination efficacy of low-energy transvenous countershock with that of pacing techniques (single extrastimuli and rapid pacing). These 25 paired episodes of VT were a subset of the total number in the study (50) subjected to attempted transvenous cardioversion. VT episodes were matched for patient, day of study, antiarrhythmic drug or drugs administered, morphologic characteristics and cycle length (230 to 465 ms, mean 342 ± 57). The method of termination first evaluated was randomly varied for each tachycardia pair. Among the paired episodes, transvenous countershock and pacing methods were comparably effective in terminating VT (21 of 25 versus 25 of 25 episodes, $p = 0.12$ by McNemar's test). Tachycardias terminated by low-energy shocks required an average of 1.53 ± 1.86 J, whereas matched episodes were converted to sinus rhythm by rapid ventricular pacing in 23 cases and single extrastimuli in 2. The cycle lengths of the 2 tachycardias terminated by single extrastimuli were well above the mean for all the pairs (400 and 465 ms). Cycle lengths ranged from 270 to 370 ms among the 4 episodes of VT not terminated by shocks of ≤5 J. Sinus rhythm was restored in 2 of these episodes by rapid pacing. The other episodes were terminated by high-energy (25 J) asynchronous transvenous countershock when VF occurred during termination attempts with synchronized shocks of 5J.

Ventricular flutter and ventricular fibrillation (Table I): In 7 patients, 2 episodes of ventricular flutter and 15 episodes of VF occurred in the course of electrophysiologic testing, whereas the catheter lead system was connected to deliver energies in excess of 5 J. Termination of VF was accomplished on every occasion with an asynchronous transvenous shock of 5 to 30 J (mean 20.4 ± 7.7) (Fig. 4B). Synchronized low-energy cardioversion of the episodes of ventricular flutter (cycle lengths 200 and 215 ms) could not be attempted because of the 220-ms refractory period of the sense amplifier in the cardioverting unit. These arrhythmias were terminated by asynchronous transvenous shocks of 12 and 10 J, respectively. Notably, asynchronous transvenous shocks did not fail to terminate any episode of ventric-

ular flutter or VF, which occurred while catheter leads were interfaced to a source of sufficient output energy (up to 30 J).

Creatine kinase measurements: Creatine kinase and creatine kinase B-subunit activity were measured as an index of possible myocardial injury, after 22 studies in 10 patients in which transvenous but not transthoracic shocks were administered. One to 13 (mean 4 ± 3) shocks of 0.01 to 30 J were administered during these studies, representing cumulative energy doses of 0.01 to 70.75 J (mean 21.68 ± 24.13). Creatine kinase activity measured 24 hours after transvenous shocks varied from 11 to 972 IU/liter, and 7 of the 22 values were elevated (120 to 972 IU/liter). Five of the elevated creatine kinase values were obtained after initial electrophysiologic studies, which were longer (4 to 6 hours) and involved the use of more electrode catheters (2 or 3) than the drug-evaluation studies that followed. Total countershock energies administered during initial electrophysiologic studies were lower, on the average, than those during drug evaluation studies (6.37 ± 10.68 versus 26.18 ± 25.32 J, $p < 0.003$). Despite some elevations in total creatine kinase activity, B-subunit activity was not increased in any determination. In addition, no patient developed persistent electrocardiographic changes after studies that involved transvenous cardioversion. These findings suggest that significant myocardial damage attributable to transvenous shocks probably did not occur. Elevations in total creatine kinase activity may have been related to tissue trauma during catheter insertions.[20]

Problems related to catheter use and transvenous countershocks: *Acceleration of VT:* During transvenous cardioversion attempts, synchronized shocks of 0.25 to 5 J accelerated VT or precipitated VF in 7 of 50 episodes (14%) of induced VT (Table II). VT acceleration occurred on 2 occasions in patient 2 after shocks of 0.25 J. In 1 instance, VT was accelerated from a cycle length of 370 to 340 ms and termination was achieved by a subsequent shock of 5 J. On the other occasion, VT was accelerated from a cycle length of 270 to 200 ms. This episode was terminated by transthoracic countershock. Synchronized shocks of 5 J percipitated VF on 5 occasions in patients 3 and 7 during attempts to terminate episodes of VT with cycle lengths of 240 to 370 ms (Fig. 4). In each instance, VF was terminated by an asynchronous transvenous shock of 15 to 30 J. Transvenous shocks that resulted in VT acceleration or VF were higher in energy than were those that did not (3.64 ± 2.32 versus 0.91 ± 1.41 J, $p < 0.001$). However, episodes of VT complicated by transvenous shock-induced acceleration or VF did not differ from other episodes with respect to cycle length (307 ± 45 versus 335 ± 65 ms, NS) or the timing of synchronization (36 ± 27% versus 36 ± 20% of the QRS interval, NS). In no instance of tachycardia acceleration or precipitation of VF had synchronization occurred after the initial 75% of the surface QRS interval.

Atrial arrhythmias: Because atrioventricular dissociation was often present during VT, catheter shocks were random in relation to atrial depolarization. Consequently, "synchronized" transvenous shocks of 0.10 to 5 J (mean 1.37 ± 1.71) initiated 2 atrial flutter episodes and 5 atrial fibrillation episodes in 7 of 47 episodes (15%) of VT, which were induced during a baseline of sinus rhythm. On all but 1 occasion, atrial arrhythmias were well tolerated and spontaneously reverted to sinus rhythm within 12 seconds to 2 hours. One episode of atrial fibrillation initiated in patient 9 was persistent and was associated with a ventricular response rate of 120. Prompt restoration of sinus rhythm was achieved in this instance by a transvenous shock of 5 J (Fig. 5).

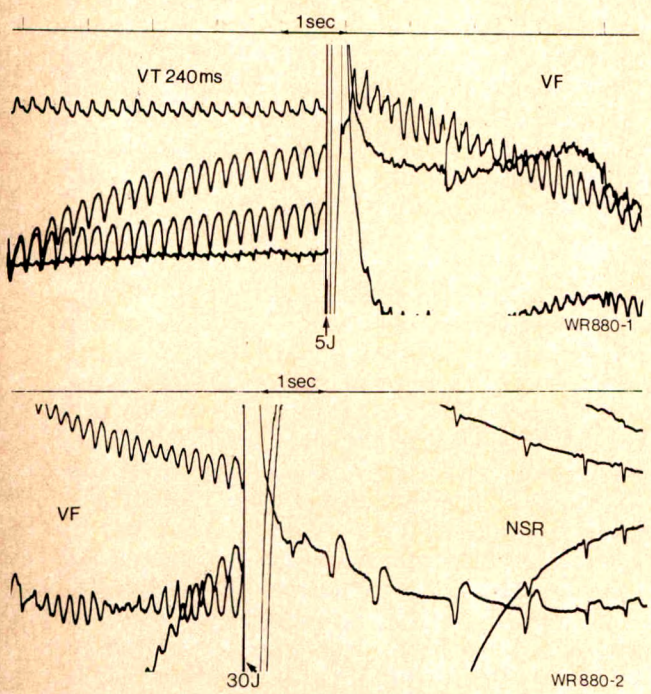

FIGURE 4. Top, Patient 3—surface lead recordings of ventricular tachycardia (VT) at a cycle length of 240 ms, which has been induced during electrophysiologic testing. Attempted cardioversion with a synchronized catheter shock of 5 J (**arrow**) produces ventricular fibrillation (VF). **Bottom,** same patient and tachyarrhythmia episode a few second later. An asynchronous transvenous shock of 30 J (**arrow**) terminates VF. Sinus rhythm (NSR) resumes after 5 complexes of a slow ventricular rhythm.

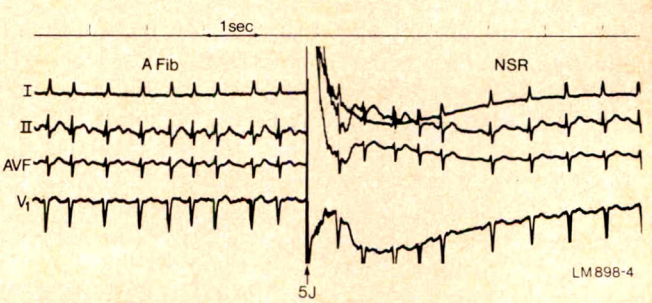

FIGURE 5. Patient 9—electrocardiographic recordings of atrial fibrillation (A Fib) with an average ventricular rate of 120, which occurred after termination of ventricular tachycardia by a synchronized transvenous shock of 1.5 J. A subsequent catheter shock of 5 J (**arrow**) restored normal sinus rhythm (NSR) after 4 complexes of an ectopic atrial rhythm.

Infection: Catheter-related infections occurred in 3 patients despite sterile precautions routinely observed during electrode catheter insertions and frequent dressing changes while leads remained in position. Patient 5 developed a cutaneous abscess over the insertion site after a catheter had been in place for 3 days. Patients 8 and 10 developed fever and bacteremia after leads had been in place for 12 and 5 days, respectively. In each case *Staphylococcus aureus* was cultured from an abscess or the blood. Neither patient with bacteremia had evidence of endocarditis, and all infections responded to catheter removal and 2 to 4 weeks of intravenous bacteriocidal antibiotics. After these infections (possibly related to the large surface area of the leads and to the electrostatic affinity of polyurethane insulation), sterile procedures were intensified to include use of a sterile mask during catheter insertion and more frequent dressing changes at the insertion site. Subsequently, no other catheter-related infections occurred.

Patient discomfort: Only shocks of ≤0.5 J were tolerated without discomfort. Patients experienced increasing discomfort when higher energies were given, and frequently requested or required sedation to tolerate countershocks >0.5 J. Nevertheless, patients who had experienced transthoracic countershock found transvenous shocks less unpleasant.

Discussion

Low-energy shocks delivered through an intravascular lead are reported to be safe and effective for terminating ventricular tachyarrhythmias that occur in a clinical setting or are induced by programmed electrical stimulation.[9–11] A system for transvenous countershock has potential advantages in situations of recurrent VT or VF, in which repeated high-energy transthoracic shocks might otherwise be necessary for arrhythmia termination.[9–11]

We assessed the safety, efficacy and patient toleration of transvenous countershock in the setting of the electrophysiology laboratory, where repeated inductions of ventricular tachyarrhythmias were expected, and compared the efficacy and patient toleration of this technique with those of other methods of arrhythmia termination. In addition, we evaluated the practicality of using a single catheter system for cardioversion and defibrillation, programmed ventricular stimulation and termination of VT by pacing methods during serial electrophysiologic testing.

Electrophysiologic testing: Catheter leads were usable for programmed stimulation at the right ventricular apex for as long as they remained in patients (up to 45 days). In addition, there were no difficulties in using leads to terminate induced VT with pacing methods on numerous occasions. We encountered no obvious lead displacements. However, the rapid increases in stimulation threshold we noted may have been related to subtle changes in distal electrode position that were not detectable on chest X-ray or fluoroscopy.

Cardioversion of ventricular tachycardia: In our study, 31 of 50 episodes (62%) of induced VT were terminated by synchronized transvenous shocks of 0.01 to 5 J. The average energy needed for these cardioversions (1.4 J) was usually tolerated by awake or mildly sedated patients. By using higher energies (10 to 30 J), an additional 7 episodes of VT were terminated, but the shocks were tolerated less well. Because conscious patients required heavy sedation before receiving intracardiac shocks of ≥10 J, high-energy transvenous cardioversion cannot be considered a preferred method for the *routine* termination of laboratory-induced VT.

When better tolerated energy levels (0.01 to 5 J) were used, transvenous countershock was unvaryingly successful only when VT cycle length exceeded 380 ms. Moreover, energy requirements for cardioversion bore no predictable relationship to tachycardia cycle length, to timing of synchronization or to indicators of catheter electrode contact with the right ventricular endocardium. Other factors not rigorously analyzed, such as antiarrhythmic drugs, heart size, and site of origin of VT in relation to lead position, may have influenced cardioversion energy requirements.[9,21]

Other investigators using similar catheter systems have reported higher incidences of VT termination with transvenous countershocks.[9,10] Zipes et al[9] terminated 47 of 49 episodes (96%) of VT using shocks of 0.025 to 2 J. Yee et al[10] found that shocks of 2.5 to 5 J terminated 12 of 16 episodes (75%) of recurrent VT in the setting of a coronary care unit. Their cardioversion rate improved to 95% (86 of 91 episodes) when energies of up to 10 J were used.[10] Differences in VT cycle length may explain the discrepancy between our results and those of Zipes et al.[9] Whereas 70% of VT episodes in the latter study[9] had a cycle length of ≥400 ms, only 7 episodes (14%) in the present study were as slow. Indeed, low-energy transvenous cardioversion was uniformly effective among our patients when VT cycle length exceeded 380 ms. VT cycle lengths were not described in the report of Yee et al[10] and, unlike the present study, most cardioversion attempts were with energies >5 J. When countershocks of ≤5 J were analyzed, the VT termination rate observed by Yee et al[10] (75%) was similar to that we found.

Previous work with catheter countershock systems demonstrated that optimal effectiveness was achieved when the distal electrode (cathode) was located at the right ventricular apex.[23] The position of the anode was less important, whether in the superior vena cava, right atrium or coronary sinus, as long as the electrode had an adequate surface area.[8,22] Because the catheter lead used in our study was designed and positioned on the basis of these considerations, the cardioversion rate we observed was probably representative of what is attainable with low energies (0.01 to 5 J).

Comparison of ventricular tachycardia termination methods: Among carefully paired episodes of laboratory-induced VT, we found no difference in rates of termination by low-energy (0.01 to 5 J) transvenous shocks and pacing methods (single extrastimuli and rapid ventricular pacing). Because paired episodes of VT were selected in that all were induced at the apex of the right ventricle, 1 of the methods of termination might have been superior in a series that included VT

induced from other right or left ventricular sites. However, the overall cardioversion rate we attained using shocks of up to 5 J (62%) was little different from the VT termination rates we[3,5] (89 to 95%) and others[2,6,7] (66 to 79%) observed using pacing methods to terminate many episodes of VT induced from several ventricular sites.

Furthermore, synchronized transvenous shocks caused VT acceleration more often than did pacing methods during attempted terminations of the paired arrhythmias (2 of 25 versus 0 of 25). When we analyzed our overall experience with methods of VT termination, intracardiac shock remained a more common cause of acceleration than pacing techniques[17] (7 of 50 episodes versus 22 of 573, $p < 0.006$ by Fisher's exact test). Thus, our data suggest that low-energy transvenous shocks are no more effective than pacing methods for VT termination, and may result in tachycardia acceleration more frequently.

Termination of ventricular flutter and ventricular fibrillation: In contrast to results during VT, transvenous countershocks were uniformly effective when used to terminate episodes of ventricular flutter and VF. Higher energies (5 to 30 J) were required to terminate these arrhythmias than most episodes of VT. Nevertheless, these energy doses were much smaller than what would have been needed for transthoracic defibrillation. Because many patients retain some level of consciousness during defibrillation attempts, transvenous countershock with relatively low energies is probably better tolerated than the alternative of transthoracic countershock.

Safety: The absence of electrocardiographic changes or elevations in creatine kinase B-subunit activity after intracardiac shocks suggests that transvenous countershocks caused no significant myocardial damage. Studies that have examined the effect of catheter shocks on the heart found that injury, when it occurred, was limited to very small areas of necrosis or endocardial hemorrhage in the region of catheter electrodes.[10,23] Because our patients and those in these studies[10,23] received similar shock energies, evidence is strong that multiple transvenous shocks at energies as high as 30 to 50 J result in little myocardial injury.

Implications: We conclude that a single catheter lead system can be used for countershock and ventricular pacing during serial electrophysiologic testing. The most practical use of a catheter system for internal countershock may be for relatively low-energy conversions (≤30 J) of repeated episodes of rapid VT or VF, in which pacing techniques are ineffective. Future systems, including implantable units, may be very useful if energy requirements for VT termination can be decreased (less discomfort), but should be capable of delivering sufficient energy to terminate accelerating VT or VF.

Acknowledgment: We extend our appreciation to Debra R. Johnston, RN, and Gale Scavin, BS, for technical assistance, Martin L. Lesser, PhD, for statistical analyses, and Lori Fields and Janet Holwell for manuscript preparation.

Significance of Prolonged Electrocardiographic Pauses in Sinoatrial Disease: Sick Sinus Syndrome

MEIR MAZUZ, MD, and HOWARD S. FRIEDMAN, MD

Eighty-four patients (2.6%) were found to have prolonged (≥2.0 seconds) sinoatrial pauses in a review of 3,259 consecutive patients who had 24-hour Holter electrocardiographic studies. Pauses averaged 2.6 ± 1.5 seconds (± standard deviation) (range 2.0–15.2). In 17 (20%), no underlying heart disease was found and in 8 (10%), prolonged pauses appeared to be drug-induced. No relation was found between length of pauses and presence of symptoms or risk of death. Twenty patients received a pacemaker. Pacemaker recipients were older and more likely to be male and to have symptoms, although 7 were asymptomatic. Patients who received a permanent pacemaker were not different from nonrecipients with respect to average longest pause, mechanisms of pause, underlying heart condition or average time of follow-up. However, the survival rate was not improved by permanent pacemaker implantation. Of the 17 patients who died, only 3 died of cardiac causes; none had a recognizable bradycardic cause. Thirteen who initially had syncope did not receive a pacemaker; 2 died of noncardiac causes and none had a subsequent syncopal episode. Ten patients with a syncopal episode received a permanent pacemaker; 3 subsequently died and 3 survivors continued to complain of dizziness. Of the 37 patients who did not have any symptoms on initial examination, only one subsequently had a syncopal episode. Thus, length of sinoatrial pauses correlates poorly with symptoms and does not predict sudden death. Unless prolonged sinoatrial pauses are shown to cause symptoms, such pauses per se are not an indication for permanent pacemaker implantation.

(Am J Cardiol 1983;52:485–489)

Disorders of sinoatrial function are the leading indication for pacemaker implantation.[1–3] Although a pacemaker would be expected to relieve symptoms caused by bradycardia, there is no evidence that life is prolonged by pacemakers implanted for sinoatrial bradycardia, even in patients with symptoms.[4–6] However, the occurrence of such bradyarrhythmias has been viewed as premonitory for Stokes-Adams attacks or even sudden death. Because of these concerns, the presence of prolonged sinoatrial pauses, even in patients without symptoms, has been suggested as an indication for pacemaker implantation.[7] Accordingly, to determine the prevalence, significance and natural history of patients with prolonged (≥2.0 seconds) sinoatrial pauses, 24-hour Holter recordings that had been analyzed at The Brooklyn Hospital were reviewed to identify patients with this condition.

Methods

Twenty-four-hour Holter recordings done at The Brooklyn Hospital between 1977 and 1981 in 3,259 consecutive patients were reviewed. Eighty-four patients (2.6%) were found to have sinoatrial pauses ≥2 seconds. In 82, clinical data at the time of the Holter study were available and in 80 of these patients, follow-up information was obtained. Twenty patients received a pacemaker; in 19, it was inserted during the same hospitalization that the Holter study was done.

Patients with electrocardiographic abnormalities were grouped as follows: Group I had sinoatrial node dysfunction (sinus bradycardia, sinoatrial block or sinus arrest). Group II had bradytachycardia syndrome with pauses upon termination of episodes of tachycardia, during tachycardia or independent of episodes of tachycardia. Group III had chronic atrial fibrillation with a slow ventricular response. Table I shows the distribution of patients into these groups.

Follow-up data were obtained from patients, relatives, private physicians and medical records. The survival rate was determined using life-table methods[8] and the differences between patients who received a pacemaker and those who did not were compared using a chi-square corrected for continuity.[9] A p value <0.05 was considered significant. Values are expressed as mean ± standard deviation.

Results

Clinical data: The patients were 30 to 104 years (average 72 ± 13). Forty-one patients were male and 43 were female. Patients who received pacemakers were older ($p < 0.05$), had a higher male distribution (chi-square = 4.7, $p < 0.05$) and were more likely to be symptomatic (Table II). There were no differences between these groups in the electrocardiographic mechanisms of pause, the underlying cardiac conditions or associated medical problems, with the exception that no patient with cancer received a pacemaker.

† Some patients had more than 1 condition.
CVA = cerebrovascular accident; SD = standard deviation.

Relationship to drugs: Prolonged pauses disappeared after discontinuing digoxin and propranolol in 2 patients, alpha methyldopa and propranolol in 1 patient, alpha methyldopa in 1, propranolol in 1, clonidine in 1, reserpine in 1 and amitriptyline and chlorpromazine in 1. In 6 patients pauses were caused by sinus node dysfunction and in 2 they were associated with bradytachycardia syndrome. Although pauses >2 seconds were not observed in these 8 patients after drugs were stopped, 2 patients with bradytachycardia syndrome and 1 with sinus node dysfunction continued to manifest electrocardiographic findings of sinoatrial disease. None of the patients with drug-induced prolonged pauses received a pacemaker. Two patients died, but in neither was the death related to the arrhythmia.

Associated conduction abnormalities: Twenty-three patients (27%) had associated atrioventricular (AV) or intraventricular conduction abnormalities or both. Nine patients had first-degree AV block, 5 second-degree AV block (4 Mobitz I and 1 Mobitz II) and 11 had right, 3 left and 3 unclassified bundle branch block. Five of these patients, including the patient with Mobitz II, received a pacemaker. Also, 24 patients with chronic atrial fibrillation and a slow ventricular response were considered to have concomitant AV nodal disease; 3 of these 24 also had an intraventricular conduction abnormality. Thus, in 44 patients (52%) with sinoatrial disease, there was electrocardiographic evidence of AV nodal or intraventricular conduction disease or both.

Symptoms: Presenting symptoms are listed in Table II. Seventeen of 82 patients (21%) had no symptoms and 25 (30%) had cardiac symptoms that could not be directly related to bradyarrhythmia. Thus, fewer than 50% of patients would have been expected to show symptomatic improvement after a pacemaker, yet 30% of pacemakers were implanted in such patients.

Relationship of pauses to symptoms: Pauses ranged from 2 to 15.2 seconds (average 2.6 ± 1.5, median 2.4). The mean of the longest pause was not a determinant of symptoms, survival or pacemaker insertion (Table III). Only 2 patients had an episode of transient loss of consciousness during the recording. Both patients had sinus bradycardia with a junctional escape rhythm and pauses ≤2 seconds. However, 16 of the 82 patients (20%) had pauses ≥3 seconds; only 2 of these patients had syncope. Six had no symptoms that could be related to their bradyarrhythmia. Four of these 16 patients received a pacemaker. Two of the 16 patients with markedly prolonged pauses died; 1 of them had received a pacemaker. Of the 3 patients with the longest pauses, none received a pacemaker, all are alive, and all are asymptomatic: The patient with a 15.2-second pause after a paroxysm of atrial flutter had no further episodes after clonidine was stopped; the patient with a 5.5-second interval of sinus arrest had no further pauses after amitriptyline and chlorpromazine were stopped; and the patient with a 4.4-second pause with atrial fibrillation continues to have pauses, but is asymptomatic.

Follow-up: Eighty patients were followed for an average of 12.8 ± 11 months (range 1 to 46); 17 (21%) died. The average survival of the 17 patients who died was 6.7 ± 7.2 months after the Holter study. Of these 17, 5 had received a pacemaker; the average survival of these 5 patients was 7 ± 4.6 months. There was no difference in the survival rate between patients who were paced and those who were not (Fig. 1). The average follow-up of patients who received a pacemaker was 14.7 ± 11 months; 25% of this group (5 of 20) died. The average follow-up of the patients who did not receive a pacemaker was 12.3 ± 11 months; 20% of this group (12 of 60) died. Thus, neither average follow-up nor likelihood of survival was different whether or not patients received a pacemaker.

The causes of death are listed in Table IV. In 1 patient the cause of death could not be determined. This patient had severe congestive heart failure with atrial fibrillation and recurrent, nonsustained ventricular tachycardia. She was admitted to another hospital before she died. Electrocardiograms at that time showed no bradyarrhythmias. Two patients died suddenly.

TABLE III Relationship of Pauses to Symptoms and Survival

	Mean ± SD	Range	Median
Patients receiving pacemakers	2.4 ± 0.5	2–3.8	2.3
Patients not receiving pacemakers	2.4 ± 0.3	2–15.2	2.4
Nonsurvivors	2.4 ± 0.4	2–3.2	2.4
All patients	2.6 ± 1.5	2–15.2	2.4
Symptoms			
Syncope	2.4 ± 0.5	2–4.2	2.2
Dizziness	2.6 ± 0.5	2–3.2	2.6
Asymptomatic or unrelated symptoms	2.8 ± 2.0	2–15.2	2.4

Values are in seconds.
SD = standard deviation

TABLE IV Causes of Death

	No. of pts.
CVA	3 (1)
Thromboembolism other than CVA	3 (1)
Renal failure	3 (1)
Metastatic cancer	2
Sudden death	2 (1)
Congestive heart failure and pneumonia	1 (1)
Aspiration pneumonia	1
Malignant hypertension	1
Unknown	1
Total	17 (5)

Parenthesis indicate number with pacemaker.
CVA = cerebrovascular accident.

They were elderly (86 and 94 years) and had unstable angina; 1 of them had received a pacemaker. No patient had a recognizable bradycardia-related death. In 6 patients, death was directly related to a thromboembolic episode and in 1 it was related to complications associated with a previous mesenteric artery thrombosis. All patients who had thromboembolism had the bradytachycardia syndrome or chronic atrial fibrillation.

Figure 2 shows the outcome of symptoms in both groups of patients. Symptoms, including syncope, generally improved whether or not the patient received a pacemaker. Five patients had recurrent syncope. In 4 patients a pacemaker was implanted. However, 1 patient who had 3 syncopal episodes before the diagnosis of the bradytachycardia syndrome did not receive a pacemaker and did not have a recurrence of this symptom.

Discussion

Since the natural history of patients with sinoatrial bradycardia is unknown, the decision to implant a permanent pacemaker in such patients is generally based on clinical intuition. Because of the widespread concern regarding the significance of the electrocardiographic findings associated with sinoatrial disease, pacemaker implantations for this abnormality have increased sharply and account in part for the recent upsurge in pacemaker implantations.[2] However, pacemakers have not been shown to prolong life in patients with sinoatrial disease. Moreover, the clinical significance of sinoatrial pauses discovered incidentally is unclear. In our study, which we believe to be the first to examine the association of the length of sinoatrial pauses to clinical manifestations, no relationship was found between the duration of sinoatrial pauses and the occurrence of symptoms, the severity of symptoms, the need for permanent pacemaker implantation or patient survival.

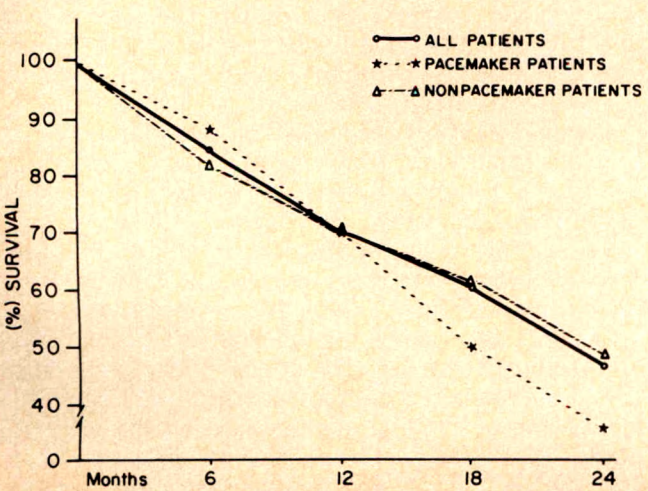

FIGURE 1. Survival rate of patients who received pacemakers compared with those who did not.

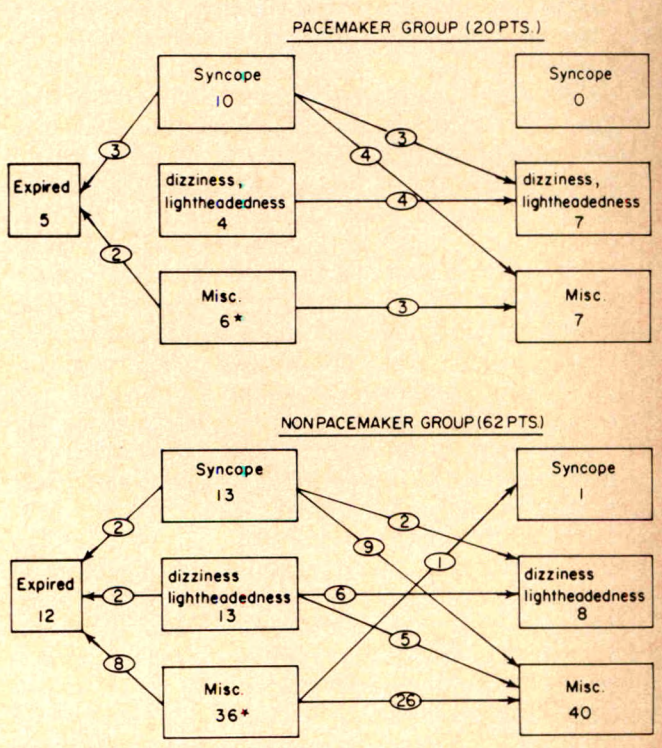

FIGURE 2. Initial symptoms and those at follow-up of patients who received pacemakers and those who did not.

While an abrupt cessation of cardiac output may result in a deficit in cerebral or coronary perfusion with its attendant effect producing either syncope or cardiac arrest, our study failed to identify a critical interval at which such events would be expected to ensue. Clearly, when such pauses produce serious symptoms, pacemaker implantation is indicated. Since the electrocardiographic manifestations of sinoatrial disease may be present for many years without adverse consequences,[10,11] the development of symptoms may be the result of systemic or regional hemodynamic changes rather than sudden, unpredictable occurrences of ventricular asystole. Whether a pause is likely to cause symptoms depends not only on the interval between heart beats, but also on the position and activities of the subject, regional vascular conditions and the capacity of the cardiac pump to generate sufficient pressure and to deliver an adequate stroke volume to maintain regional flow between cardiac cycles.

Prolonged sinoatrial pauses were observed in 2.6% of the patients in our study. Since these recordings were from patients at high risk for heart disease, this incidence might not reflect that found in otherwise healthy subjects. Brodsky et al[12] found sinoatrial pauses >1.75 seconds in 14 of 50 (28%) male medical students who had 24-hour Holter recordings. Viitaslo et al[13] found sinoatrial pauses >2 seconds on recordings from 13 of 35 (37%) endurance athletes and also in 2 of 35 (5.7%) matched nonathletic controls. Moreover, the electrocardiographic findings of sinoatrial disease may be present for many years in asymptomatic subjects.[13] Thus, presence of prolonged sinoatrial pauses per se cannot be considered to be an indication of cardiac malfunction.

To be viewed as beneficial, a pacemaker must improve survival or at least alleviate symptoms. Clearly, many patients with symptoms caused by sinoatrial disease obtain relief after pacemaker implantation.[5,14–17] However, pacemaker implantation has been suggested for asymptomatic subjects who have an arbitrarily selected slow heart rate or sinoatrial pause.[5,7] In our study, <50% of patients with prolonged sinoatrial pauses had symptoms that could be related to their bradyarrhythmia, yet 30% of pacemakers were implanted in such patients. Furthermore, implantation of pacemaker did not ensure that symptoms would improve. Seven of 20 patients (35%) who received a pacemaker continued to have central nervous system complaints after pacemaker implantation. This finding is in accord with an earlier report from our hospital that indicated that even after a critical policy of pacemaker implantation was instituted, 9% of patients who had a permanent pacemaker continued to have symptoms similar to those before implantation.[2] Previous reports have also shown that pacemakers do not always relieve symptoms in patients with sinoatrial disease.[6,18–21]

However, symptoms may spontaneously abate. In our study, 14 of 26 patients (54%) with symptoms ascribed to sinoatrial pauses who did not receive a pacemaker showed symptomatic improvement on follow-up. Similarly, Gann et al[5] found that 9 of 10 patients with syncope who did not receive a pacemaker had no further episodes during an average follow-up of 4.6 years. Rokseth and Hatle[6] observed that in 17 of 36 patients with syncope associated with sinoatrial disease, no treatment was considered necessary because either a single syncopal attack had occurred or slight symptoms persisted.

The electrocardiogram of sinoatrial disease may change over time.[5] Periods of electrocardiographic normalization[22] or a change to a stable chronic atrial fibrillation may eliminate the need for a permanent pacemaker in some patients.[23] The development of a stable chronic atrial fibrillation has been reported to occur in 11–37% of patients with sinoatrial disease.[16,19,23–25] Also, since both bradycardia and central nervous system symptoms are common in an elderly population, the failure of a pacemaker to produce symptomatic improvement may have been due to incorrectly attributing symptoms to the electrocardiographic abnormality.

Pacemaker implantation has not been shown to improve survival in patients with sinoatrial disease. Our study is consistent with previous reports.[4–6] Moreover, none of the deaths in our patients who did not receive a pacemaker could be ascribed to a bradycardic event. Previous studies, in fact, have not demonstrated a high risk of sudden death in patients with sinoatrial disease, and the occurrence of a bradycardia-related cardiac arrest appears to be rare in such patients. Our studies and previous natural history[11,14,22] and pacemaker follow-up studies[15–20,24,25] support the view that the survival of patients with sinoatrial disease is primarily determined by whether there is concomitant coronary disease, heart failure or systemic disease. The mortality rate in our patients appears to be a result of the high percentage of patients derived from a hospital population, in whom an increased incidence of severe systemic disease would be expected.

The limitation of our study and previous similar investigations is that they have been retrospective and nonrandomized. There may be an inherent bias in which patients who receive a pacemaker are likely to have more severe cardiac disease than those who do not. Such selection might obscure the possible beneficial effect of a pacemaker. In any case, although the issue is still unsettled, the evidence available fails to support the view that pacemakers improve survival in patients with prolonged sinoatrial pauses.

Clinical implications: Based on our experience and previous reports, the following approach to the management of prolonged sinoatrial pauses is suggested: Patients without symptoms do not require therapy. Nonessential bradycardia-producing drugs should be discontinued in symptomatic patients. Patients with bradytachycardia syndrome with prolonged pauses after episodes of tachycardia should receive a trial of antiarrhythmic therapy. Some patients may require such trials in a setting of continuous electrocardiographic monitoring or even with a temporary pacemaker in place. In symptomatic patients, especially when symptoms are vague and nonrepetitive, a clear relationship between the electrocardiographic abnormality and symptoms should be demonstrated. The role of

electrophysiologic studies in such patients is not clear because the studies have not been sufficiently reliable to predict which patients with sinoatrial disease require a pacemaker.[26] Perhaps such studies should be reserved for patients suspected of having occult tachyarrhythmias as an explanation for symptoms.

Acknowledgment: Appreciation is expressed to Dr. Balendu C. Vasavada, who reviewed many of the Holter recordings used in this study, and to Daisy Frankson for her capable secretarial assistance.

Cardiac Arrhythmia and Conduction Disturbances During Sleep in 400 Patients With Sleep Apnea Syndrome

CHRISTIAN GUILLEMINAULT, MD, STUART J. CONNOLLY, MD, and
ROGER A. WINKLE, MD

This report presents the first study of cardiac arrhythmias and conduction disturbance in a large group (400 patients) with sleep apnea syndrome studied between 1974 and 1979 with 24-hour Holter electrocardiography and a simultaneously recorded polygraph during late afternoon or nocturnal sleep. Of the 400, 193 patients (48%) had cardiac arrhythmias during the recorded night. The mean number of apneic events, age, weight and lowest oxygen saturation during sleep were not significantly different in those with arrhythmias.

The most significant abnormalities were unsustained ventricular tachycardia in 8 patients, sinus arrest that lasted for 2.5 to 13 seconds in 43 patients, and second-degree atrioventricular conduction block in 31. Seventy-five had frequent (>2 beats/min) premature ventricular contractions during sleep. Fifty patients with significant arrhythmias had a tracheostomy and were monitored again after surgery. No arrhythmia was present in these patients except for premature ventricular contractions.

(Am J Cardiol 1983;52:490–494)

In 1965 Gastaut et al[1] reported that some pickwickian patients had apnea during sleep.[1] In 1972, at the first international meeting on sleep apnea in Rimini, Italy, 3 teams presented hemodynamic studies on different kinds of patients with sleep apnea.[2–4] Each team showed that systemic blood pressure or pulmonary arterial pressure, or both, increased during sleep with sleep-related apnea. In 1977, we reported on cardiac arrhythmias occurring during sleep in 15 patients with sleep apnea syndrome. Fourteen of the 15 patients with obstructive sleep apnea syndrome had significant cardiac arrhythmias during sleep, although electrocardiograms (ECG) during wakefulness were normal.[5] Miller[6] also recently reported cardiac arrhythmias in 23 patients with sleep apnea. This is the first large study (400 patients) of the incidence and nature of cardiac arrhythmias during sleep in patients with sleep apnea syndrome.

Methods

Patient group: The 400 patients surveyed included 16 women and 384 men with sleep apnea syndrome who met the following criteria: (1) they were seen at the Stanford Sleep Disorders Clinic between 1974 and 1979; (2) they had undergone simultaneous 24-hour Holter ECG and nocturnal polygraph recording; and (3) they were diagnosed as having sleep apnea syndrome (a score of >5 on the Apnea-Hypopnea Index).[7] During the same period, 187 patients seen in our clinic were rejected because they did not meet all the criteria. Retrospective investigation of these 187 patients showed that 111 of them had an apnea/hypopnea index of 5 to 40. The 400 analyzed subjects, who had an apnea/hypopnea index of 25 to 92, were, overall, more severely affected than the group excluded from the study. The women were 25 to 68 years old (median 59) and the men were 19 to 71 years (median 48). All subjects were referred for a sleep problem: 348 for daytime somnolence, 24 for disrupted nocturnal sleep, and 28 for heavy snoring at night and/or spousal observation of apneic events during sleep without significant sleep complaint. Of the 400, 354 (88.5%) had no other clinical syndrome associated with sleep apnea; 288 of these (72%) were 30 to 250% overweight. Forty-six nonobese subjects had sleep apnea syndrome associated with another condition: 12 acromegaly, 5 goiters, 1 Hodgkin's disease, 2 had received neck irradiation for other types of cancer, 3 Shy-Drager syndrome, 6 significant kyphoscoliosis (5 of these secondary to poliomyelitis), 8 myotonic dystrophy, 1 syringobulbomyelia, 6 micrognathia, and 2 Treacher-Collins' syndrome.

Cardiovascular disease and risk factors in the study group: Systemic hypertension had been diagnosed in 197 subjects (49%). In 20%, blood pressure was controlled by diet and nondrug treatment. During the previous 36 months, 117 subjects (29%) had taken antihypertensive medication. At the time of this study, 109 subjects had a blood pressure (supine) of ≥140 mm/Hg systolic and 90 mm/Hg diastolic. Sixty-nine subjects were receiving a diuretic medication (mostly chlorothiazide type) and 29 were taking propranolol hydrochloride. Late-onset, noninsulin–dependent diabetes had been diagnosed in 22 overweight subjects. Seven patients had had a myocardial infarction during the past 9 years; 8 were being treated for angina pectoris, and 12 had been hospitalized for unexplained chest pain. Four subjects had cardiac pacemakers implanted before consultation with the sleep clinic, 2 of whom had been referred immediately after pacemaker implantation because of their excessive daytime sleepiness. No patient was referred for a cardiovascular problem. Amphetamine had been prescribed for 161 subjects, and an additional 85 had had both amphetamine and methylphenidate prescribed for their daytime sleepiness. These two medications were discontinued at least 15 days before the investigation.

Fifty patients with severe sleep apnea syndrome underwent tracheostomy and were restudied 3 to 6 months after surgery with nocturnal polygraphic recordings and 24-hour Holter electrocardiogram.

Protocol: Each patient had a complete physical examination and a 12-lead ECG within 4 weeks of the first nocturnal investigation. At least 1 nocturnal polygraphic monitoring recorded the following variables: electroencephalogram (C3/A2—C4/A1 of the 10–20 international placement system), electrooculogram, digastric electromyogram and electrocardiogram (lead II). Respiration was monitored using oral and nasal thermistors and abdominal and thoracic mercury strain gauges or respiratory inductive plethysmography (Respitrace®). Arterial oxygen saturation was measured using a Hewlett-Packard ear oximeter (model 47201A).[8] The 24-hour Holter electrocardiographic recordings began between 12 and 4 PM on the day of nocturnal monitoring. The 24-hour ambulatory electrocardiographic recording was performed with an Avionics electrocardiographic tape recorder. All electrocardiographic tapes were processed by the Stanford computer-assisted method.[9,10] This technique enables accurate detection of all arrhythmias. The Holter electrocardiographic tracing and the polysomnogram were synchronized using the electrocardiographic lead on the sleep recording (Fig. 1). Polysomnograms were scored in 30-second epochs following Rechtschaffen and Kales' manual for scoring sleep states and

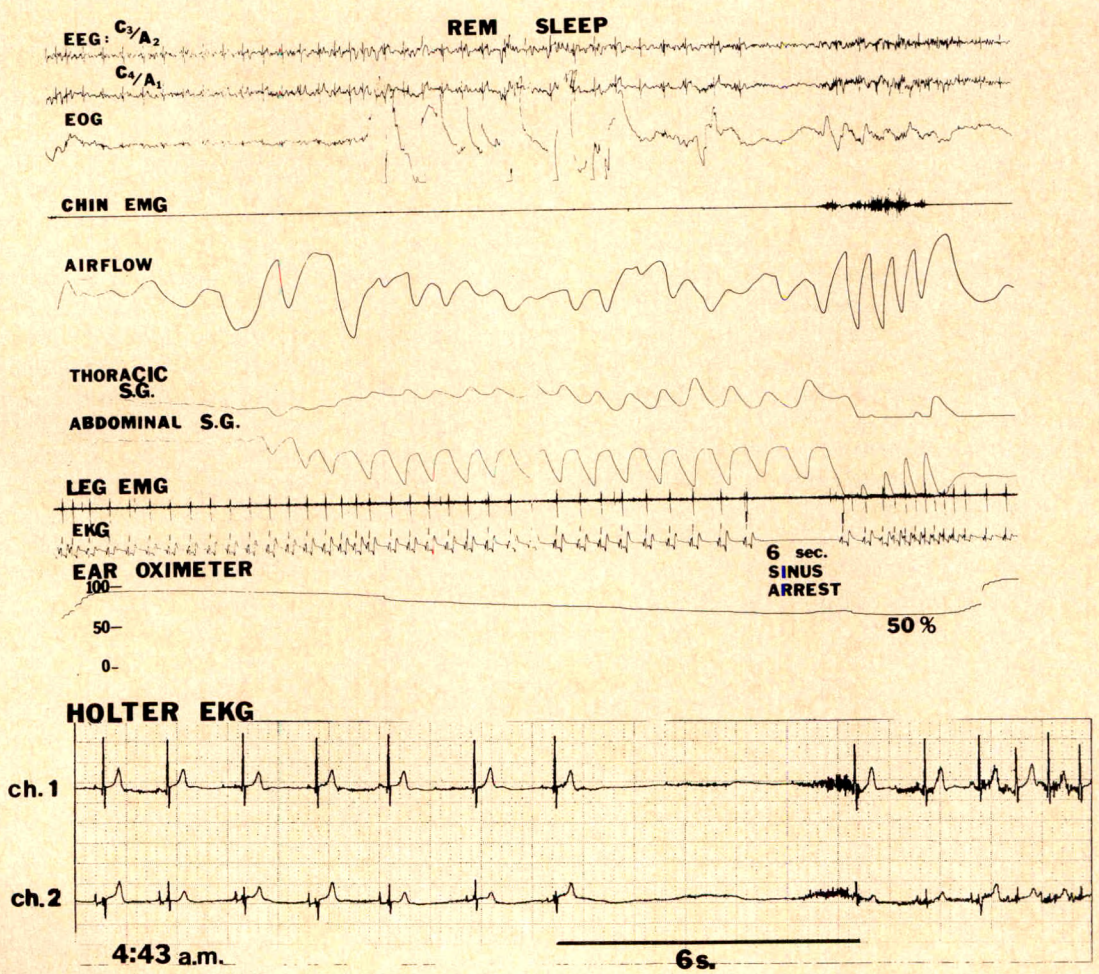

FIGURE 1. Segments of a polygraphic recording and Holter electrocardiogram (EKG) obtained from a 43-year-old man at 4:43 AM during REM sleep. Using the times written on both recordings, one can identify cardiac arrhythmias. With the polygraphic recording, one can correlate cardiac arrhythmias with sleep stages, sleep states, oxygen saturation and type of apnea. With the Holter electrocardiogram, one can accurately detect all arrhythmias and play back the tape for analysis at conventional speed. EEG = electroencephalogram; EMG = electromyogram; EOG = electrooculogram; SG = strain gauge.

TABLE I Cardiac Arrhythmias and Conduction Abnormalities Seen During Sleep in Association With Sleep Apnea Syndrome

Arrhythmia or Conduction Abnormality	Percent of Total Population	Patients (n)
Sinus arrest (2.5 to 13 s)	11	43
Second-degree atrioventricular cardiac block		
Mobitz type I	5	19
Mobitz type II	3	12
Ventricular tachycardia	3	12
Atrial tachycardia	7	28
Sinus bradycardia (<30 beats/min for at least 10 s)	7	29
Paroxysmal atrial fibrillation	3	10
Paroxysmal atrial flutter	1	3
Frequent premature ventricular contractions (>2/min)	20	75*

* Only 40 patients had premature ventricular contractions not associated with other arrhythmia during sleep.

TABLE II Cardiac Arrhythmia or Conduction Abnormality in 50 Patients With Sleep Apnea Syndrome Before and After Tracheostomy

Cardiac Arrhythmia or Conduction Abnormality	Before Tracheostomy		After Tracheostomy	
	Awake	Asleep	Awake	Asleep
Sinus arrest 4 to 13 s	0	15	0	0
Second-degree atrioventricular block				
Mobitz type I	0	5	0	0
Mobitz type II	0	10	0	0
Ventricular tachycardia	0	8	0	0
Atrial flutter	0	2	0	0
Atrial fibrillation	0	8	0	0
Extreme sinus bradycardia	0	2	0	0
Frequent premature ventricular contractions (>2/min)	6	18*	4	4

* A number of patients had several types of cardiac arrhythmia: 4 with runs of ventricular tachycardia also had frequent premature ventricular contractions (>2/min); 8 patients with second-degree block; 2 with atrial fibrillation; and 2 with sinus arrest also had premature ventricular contractions. Two patients had sinus arrest in association with extreme sinus bradycardia (heart rate <30 beats/min). Only 2 patients presented frequent premature ventricular contractions independent of other arrhythmias.

stages.[11] Apneic and hypopneic episodes were identified and scored using the criteria of Guilleminault et al[7] (defined as the number of abnormal respiratory events divided by total sleep time and multiplied by 60). Hypopnea was defined as a decrease of air exchange at the nose and mouth with increased thoracoabdominal movements (incomplete airway obstruction) or decrease of thoracoabdominal movement with decrease of airflow, in both cases accompanied by a simultaneous decrease in oxygen saturation.[7]

Results

Cardiac arrhythmias or conduction disturbances were present during sleep in association with sleep apnea in 193 patients (48%). The mean age of affected patients was 49 years; all but 1 were male, and 84% were obese. They had a mean apnea-hypopnea index of 42 (range 25 to 88). The lowest oxygen saturation during sleep in individual patients ranged from 30 to 64% (H-P ear oximeter values).[8] There were no important differences in age, body weight, apnea-hypopnea index or minimum oxygen saturation between those with and those without arrhythmias (Wilcoxon matched pair rank test). The incidence of hypertension and of diuretic or beta-blocking drug intake was similar in both groups.

Among the other 207 patients (without cardiac arrhythmias during the monitoring night), the lowest apnea-hypopnea index was 20 and the highest 92. The mean apnea-hypopnea index was 42.8. The lowest oxygen saturation measured during sleep varied between 62% and <30%.[8] Fewer patients in the arrhythmia group had angina pectoris or had had a myocardial infarction (2 versus 13). The small subgroup of patients (10%) with predominantly central sleep apnea were different from those with obstructive apnea in that only 1 had any arrhythmia other than premature ventricular contractions (PVCs) (a 6-second sinus node arrest). Except for PVCs, cardiac arrhythmias were only seen when the oxygen saturation was <72%, and 93% of these were observed with an ear oximeter reading ≤65%. These arrhythmias always occurred during the second half of an apneic event, and 98% occurred during an obstructive event or during the obstructive phase of a mixed apneic event.

Eight patients had a single episode of unsustained ventricular tachycardia 5 to 11 beats in duration (Table I). Sinus node arrest (2.5 to 13 seconds) occurred in 43

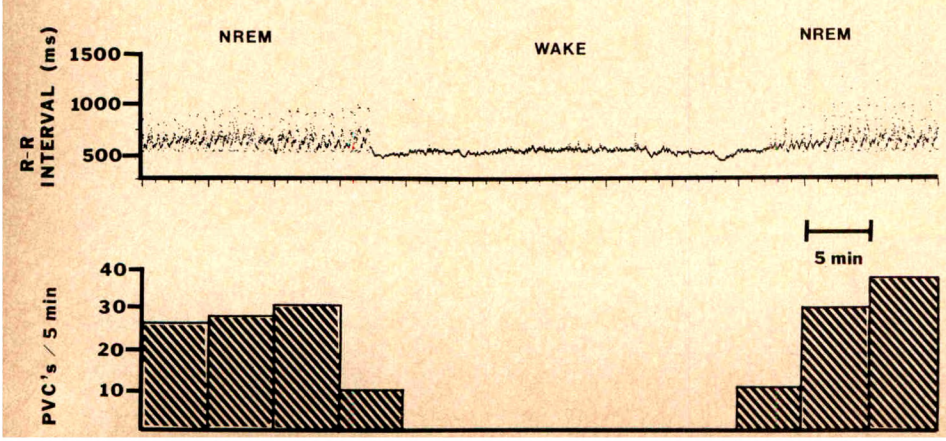

FIGURE 2. The relation between the frequency of premature ventricular contraction (PVCs) and sleep. Each **dot** in the **upper panel** shows 1 R-R interval. The **lower panel** shows the frequency of premature contractions. Note the cyclic pattern of R-R intervals during non-REM (NREM) sleep associated with sleep apnea. PVCs decrease greatly on waking.

patients; in 32 patients it was ≥4 seconds in duration. Second-degree atrioventricular nodal conduction block occurred in 31 patients; 19 had Mobitz type I and 12 had Mobitz type II. All episodes of ventricular tachycardia, sinus arrest, and second-degree atrioventricular block occurred only during obstructive sleep apnea in stage 2 sleep or in REM sleep. Frequent PVCs (2/min) during sleep occurred in 75 patients (20%), 35 of whom also had other arrhythmias during sleep. In 55 patients, PVCs were clearly sleep-related and their frequency decreased when the patients awoke, even for short periods of time (Fig. 2). In the subgroup of patients with a previously known cardiac problem (myocardial infarction or angina) and sleep apnea, 2 patients had more frequent PVCs during wakefulness than during sleep. Except for PVCs, no patient with significant cardiac arrhythmia during sleep had any arrhythmia during wakefulness. Sinus arrest was seen in 3 patients who had extreme sinus bradycardia at other times during the night. Extreme sinus bradycardia occurred concurrently with obstructive sleep apnea during nonREM sleep in these 3 patients, whereas sinus arrest was noted during REM sleep. The REM sleep apneic events leading to asystoles were no longer than those leading to extreme sinus bradycardia.

Cardiac arrhythmia and tracheostomy: Fifty patients with arrhythmias during sleep apnea underwent tracheostomy, 37 of whom have been reported previously.[12] The number of cardiac arrhythmias and conduction abnormalities occurring during sleep and while awake both before and after tracheostomy are presented in Table II. Three to 6 months after successful tracheostomy, no arrhythmia or conduction abnormality was detected in 46 patients during sleep on electrocardiographic Holter recordings. Frequent PVCs were still present in 4 patients during the 24-hour period, but decreased during sleep in all 4.

Discussion

This study demonstrates that cardiac arrhythmias and conduction abnormalities commonly occur during sleep in patients with sleep apnea syndrome. To assess the importance of rhythm disturbances that were found in the patients in this study, it is helpful to compare the frequency with which arrhythmias are recorded by 24-hour Holter electrocardiography in large groups of healthy subjects without diagnosed sleep apnea. Several studies have shown that sinus arrest lasting longer than 2.5 seconds and sinus bradycardia of <30 beats/min do not occur in asymptomatic, healthy subjects,[13–17] although 0.7 to 6% of asymptomatic subjects have some episodes of second-degree atrioventricular nodal block, predominantly Mobitz type I. The sinus arrest and extreme bradycardias that occur in some patients with sleep apnea is abnormal and is a potentially life-threatening complication of sleep apnea syndrome.

Frequent PVCs and episodes of nonsustained ventricular tachycardia are both reported to occur in asymptomatic subjects studied by Holter electrocardiography. Frequent PVCs are seen in 0 to 12% and ventricular tachycardia in 0 to 4% of subjects; the frequency of both arrhythmias appears to increase with age,[13–17] even in patients who have been screened for heart disease. Both PVCs and ventricular tachycardia were more frequent during periods of wakefulness than during sleep in these population surveys, and when they did occur nocturnally, sleep apnea syndrome (a condition frequently overlooked) was not specifically excluded. Frequent PVCs were detected in 20% of our patients, a higher incidence than that reported for asymptomatic populations. However, we had more cases of obesity and hypertension in our patients. Both our patients and the reported asymptomatic subjects had a similar incidence of ventricular tachycardia (4%). In our study, however, all 8 episodes of ventricular tachycardia occurred during a sleep apneic event. This is in marked contrast to the general daytime occurrence of frequent PVCs and episodes of ventricular tachycardia in studies of asymptomatic subjects.[13–16] More than half of our subjects with frequent PVCs and bigeminy and trigeminy had predominantly nocturnal PVCs, suggesting a relation between arrhythmias and sleep apnea. Our study raises the possibility that the occurrence of arrhythmias in asymptomatic population groups may in some cases be related to sleep apnea syndromes. Without systematic interviews to evaluate sleep behavior, patients with sleep apnea may be included in surveys of "normal" populations.

Fifty patients in this study underwent tracheostomy. After surgery, no patient had arrhythmias other than PVCs, further supporting the contention that the sleep apnea episodes caused the arrhythmias.

The sinus and atrioventricular nodes are strongly influenced by autonomic tone; atrial and ventricular arrhythmias are affected by neurologic, psychologic and autonomic factors.[18] The autonomic activity present during sleep may affect the heart.[19] During sleep apnea episodes, there is evidence of heightened autonomic activity.[20] The mechanism by which sleep apnea causes arrhythmias is not known, but autonomic nervous system imbalance and arterial oxygen desaturation are likely to be important factors. In some patients, underlying cardiac disease may also contribute to the arrhythmias.

In summary, we found cardiac arrhythmias (some potentially life-threatening) to be common in patients with sleep apnea syndrome. These almost always occurred in association with an episode of obstructive apnea. Tracheostomy eliminates both the sleep apnea and the arrhythmias.

Encainide for Refractory Ventricular Tachyarrhythmia

BRIAN CHESNIE, MD, PHILIP PODRID, MD, BERNARD LOWN, MD, and ERNST RAEDER, MD

Encainide, a new antiarrhythmic agent, was studied in 80 patients with sustained ventricular tachycardia or ventricular fibrillation. Drug efficacy was evaluated by ambulatory monitoring and exercise testing in 63 patients who had frequent or repetitive ventricular premature beats and by means of electrophysiologic testing in 17 patients who did not have significant arrhythmia during a 48-hour control period. Encainide was effective in 36 of 63 patients (57%) as judged by ambulatory monitoring and in 35 of 51 patients (69%) who had exercise tests while taking the drug. Overall, 34 patients (54%) responded to encainide when evaluated by both monitoring and exercise testing. The drug was effective in 7 of 16 patients (44%) who underwent electrophysiologic studies. Daily doses and blood levels of encainide were comparable in responders and nonresponders. Toxicity occurred in 24 patients (30%) and included nausea, vomiting, headaches, lethargy, tremors and conduction disturbances. In 18 patients (23%) arrhythmia was aggravated. An increase in arrhythmia correlated with larger daily doses of encainide and higher serum blood levels of encainide and its metabolite OD-methyl-encainide, but did not correlate with QRS- or QT-interval widening. Of the 27 patients who were discharged on encainide, 23 were maintained on the drug for an average of 21 months (range 12 to 44). Three patients died suddenly.

Thus, encainide is a useful agent for suppression of malignant ventricular arrhythmias. However, it has a high potential for worsening arrhythmias and careful evaluation by both monitoring and exercise testing is necessary to judge its effect.

(Am J Cardiol 1983;52:495–500)

An increasing number of patients with life-threatening ventricular arrhythmias are being identified and are in need of treatment. This has stimulated the introduction of a number of antiarrhythmic drugs that are undergoing active investigation. One such agent is encainide, a newly developed benzanilide derivative with promising antiarrhythmic properties in short-term animal studies.[1,2] In isolated canine cardiac Purkinje fibers, encainide exhibits potent local anesthetic properties or membrane-stabilizing effects.[3] At concentrations of $>10^{-5}$ mol, encainide exerts significant depressant action, resulting in reduced action potential amplitude and upstroke velocity (dV/dt max). Action potential duration is shortened, the refractory period is unaffected and automaticity is decreased. Several studies involving a small number of patients have reported that encainide was effective in suppressing ventricular arrhythmias unresponsive to standard antiarrhythmic drugs.[4–7] This report presents results of encainide in a large group of patients with diverse forms of heart disease who experienced frequent, symptomatic ventricular arrhythmia refractory to conventional drugs.

Methods

Patients: The group consisted of 80 patients, 59 men and 21 women, with an average age of 54 years (range 19 to 76) (Table I). All patients had documented malignant, sustained and recurrent ventricular arrhythmias. The term malignant defines a group with life-threatening arrhythmias consisting of either ventricular fibrillation (VF) or sustained ventricular tachycardia (VT) manifested by serious hemodynamic compromise and requiring countershock or antiarrhythmic drugs for termination. Patients whose VT was either transient or unaccompanied by symptoms were not included in this study. In the present group persistent VT resulted in syncope in 28 patients or hypotension and dizziness in 31. Twenty-one of the 80 patients experienced VF from which they have been successfully resuscitated. These patients had been referred for medical management because of their refractoriness to conventional agents including procainamide, quinidine, disopyramide and propranolol. The arrhythmia was considered to be refractory to a drug if a sustained episode recurred at a

time when the drug level was within the therapeutic range. Cardiac diagnoses included coronary artery disease in 45 patients, 42 of whom had a history of a remote myocardial infarction; cardiomyopathy in 11; and valvular heart disease in 8. In 16 patients no heart disease was seen on cardiac catheterization or echocardiography. Forty-five patients (56%) had a history of congestive heart failure and exhibited cardiomegaly on the chest roentgenogram. At the time of study all were hemodynamically compensated and were receiving maintenance digoxin or diuretic therapy.

Protocol: *Control studies:* On admission to the hospital all cardioactive drugs were discontinued. Digoxin was maintained when congestive heart failure had been historically documented. After 36 to 48 hours off the drug, control studies were performed. These consisted of 48 hours of continuous ambulatory electrocardiographic monitoring and maximal exercise testing on a motorized treadmill adhering to a Bruce protocol.[8] The details of this control phase of the study have been described.[9,10]

Ventricular premature beats (VPBs) were categorized according to the Lown grading system[9,11]: grade 0: no VPBs; grade 1A: ≤30 VPBs, ≤1/min; grade 1B: ≤30 VPBs, >1/min; grade 2: >30 VPBs; grade 3: multiform VPBs; grade 4A: repetitive VPBs (couplets); grade 4B: repetitive VPBs (ventricular tachycardia); and grade 5: early (R on T) VPBs.

Evaluation of therapy: The protocol to be followed was determined by the frequency and type of ventricular arrhythmia present during control studies.[10] Noninvasive antiarrhythmic drug evaluation was performed if the following arrhythmias were exposed: during monitoring, grade 2 VPBs during at least 50% of monitored hours, and grade 4 VPBs for at least 3 of the 24 hours; during exercise testing, at least 2 VPBs/min during the entire exercise test, and grade 4 VPBs during exercise or recovery periods.

If these criteria were not met, the patient underwent electrophysiologic studies.[12] Under fluoroscopic guidance, a No. 6Fr hexapolar pacing catheter was inserted percutaneously into the left subclavian vein and positioned at the right ventricular apex. The catheter was sutured to the chest wall so that its position was stable. Programmed premature stimulation was performed using ≤3 successive extrastimuli at energies of 2 and 3 times the mid-diastolic threshold. Studies were carried out during both sinus rhythm and ventricular pacing at a cycle length of 500 ms. The end point for the electrophysiologic study was the provocation of nonsustained VT, defined as ≥3 successive ventricular beats occurring after the last premature beat provoked by programmed stimulation. In all cases this end point was reproducible, being induced at least twice at the same coupling cycle.

Protocol for drug administration: At the conclusion of baseline studies, oral encainide therapy was initiated, adhering to the following schedule: On day 1 an acute drug test[9,10] with oral encainide was carried out. During a 30-minute control period the electrocardiogram was continuously recorded by trendscription[13] and exercise was performed on a bicycle ergometer for 5 minutes. At the conclusion of this control period 75 mg of encainide was administered as a single oral dose. The electrocardiogram was continuously monitored and recorded for 3 hours. Each hour a 5-minute bicycle exercise was repeated and a lead II and V_3 rhythm strip recorded at 50 mm/s for a measurement of electrocardiographic intervals. Eight hours after this dose, 25 mg of encainide was administered. On day 2, the dosage was 20 or 25 mg 4 times daily; on day 3, 20 or 25 mg alternating with 50 mg 4 times daily; on day 4, 50 mg 4 times daily; on day 5, 50 mg alternating with 75 mg 4 times daily; and on day 6, 75 mg 4 times daily.* Patients were observed in a special care unit and were seen daily by the medical staff as well as by one of the investigators and a research nurse-clinician. During encainide administration, patients were continuously monitored by telemetry and the rhythm was recorded by means of trendscription. Each day before a change in the dose of encainide patients performed on a bicycle ergometer for 5 minutes, and leads II and V_3 rhythm strips at 50 mm/s were obtained for electrocardiographic intervals. At least 3 complexes were measured. Patients were questioned carefully to ascertain the occurrence of adverse effects. A decision to increase the dose of encainide depended on the absence of adverse effects and the persistence of arrhythmia on trendscription or during bicycle exerise. If adverse effects developed, the dose was decreased to that tolerated. The response to therapy was evaluated after at least 48 hours of treatment with a stable dose. Blood levels for encainide and OD-methyl-encainide levels were determined 2 hours after drug administration.

The response to encainide was evaluated either with noninvasive techniques that included both exercise testing and ambulatory monitoring or with invasive electrophysiologic testing.

On the basis of our experience with management of patients with malignant ventricular arrhythmia,[14] encainide was deemed effective if the following 3 criteria were fulfilled for noninvasive evaluation with both monitoring and exercise testing: total elimination of grade 4B and 5 VPBs; ≥90% reduction in the frequency of grade 4A arrhythmia (couplets); and ≥50% decrease in the number of hours during which grade 2 arrhythmia occurred with monitoring and >50% reduction during exercise testing.

The criterion for drug efficacy with electrophysiologic testing was the inability to provoke multiple repetitive ventricular responses (>2) during either sinus rhythm or ventricular pacing using up to 3 successive premature stimuli at 3 times mid-diastolic threshold.[12] Encainide was considered effective if only a single repetitive response was elicited. The cycle length used was the same as during control study.

Long-term therapy: Initiation of chronic therapy with encainide depended on 3 factors: fulfillment of criteria for efficacy, absence of significant adverse effects, and encainide considered the most effective and best tolerated of all the drugs tested. Patients were followed up every 1 to 2 months with repeat monitoring, exercise testing, and blood sampling for chemistries as well as for encainide and the metabolite OD-methyl-encainide.

Statistical analysis was performed with the *t* test for paired data and the chi-square test. All results were expressed as mean ± standard deviation and the level of significance was $p < 0.05$.

*After the first 10 patients in the study, 50 mg 4 times daily was established as the maximal dose by the sponsoring pharmaceutical company, Mead Johnson.

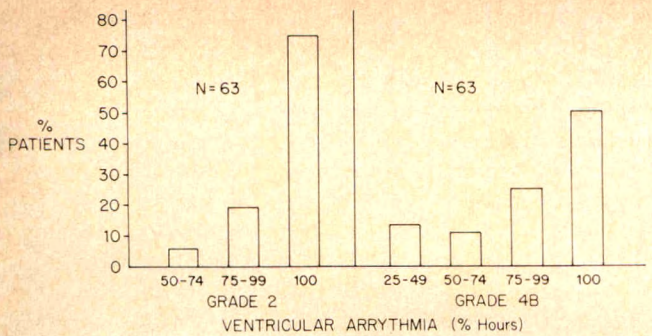

FIGURE 1. Frequency of grades 2 and 4 ventricular arrhythmia during control studies among the 63 patients who underwent noninvasive evaluation of encainide. All patients had frequent ventricular premature beats (grade 2) for >50% of the monitored hours, whereas 48 patients (75%) had grade 2 for all hours (**left**). All patients had ventricular tachycardia (grade 4B) for >25% of the hours monitored (**right**), and in 32 patients (50%) these forms were present during each hour.

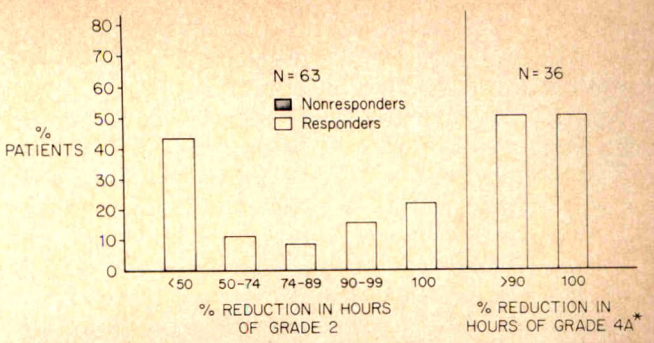

FIGURE 2. Results of encainide therapy as evaluated by 24-hour ambulatory monitoring. Encainide was ineffective in 43% of patients (**left**). In the 36 responders (57%), the hours of frequent ventricular premature beats (grade 2) was decreased by >75% in 24 patients, whereas grade 2 arrhythmia was abolished during all hours in 14. Grade 4 arrhythmia was entirely abolished in 18 patients, whereas all grade 4B was eliminated and grade 4A reduced >90% in 18. *All patients had total elimination of 4B.

Results

Control studies: Of the 80 patients treated with encainide, 63 had noninvasive evaluation for drug efficacy with exercise testing and monitoring and 17 underwent invasive electrophysiologic studies.

In all 63 patients who had noninvasive studies, control monitoring demonstrated frequent salvos of VT, and in 54 (86%) such paroxysms were present during >50% of the hours monitored (Fig. 1). In 59 patients (94%) frequent VPBs (grade 2) were present during >75% of the hours.

Of the 51 patients who underwent exercise testing, all exhibited frequent VPBs (mean frequency 230, range 100 to 540) and couplets (mean 21 per test). In 35 of these patients salvos of VT were provoked as well. The remaining 12 patients did not undergo exercise testing because of frequent salvos of VT with hemodynamic instability that occurred in the coronary care unit after antiarrhythmic drugs were discontinued.

Of the 17 patients who underwent electrophysiologic testing during control study, 5 had nonsustained VT (average 8 cycles, range 6 to 12). Eleven patients responded with sustained VT (average rate 193, range 160 to 280) and 1 patient had VF. One additional patient required cardioversion because of hemodynamic instability, and in 10 overdrive pacing terminated the VT.

Drug efficacy with noninvasive evaluation: Encainide was effective in 36 of 63 patients (57%) when evaluated by ambulatory monitoring. In 18 of these patients grade 4 or repetitive VPBs were entirely abolished and in the other 18 grade 4B was eliminated, grade 4A was reduced by ≥90% and the number of hours of grade 2 was reduced by ≥50%. Twenty-four patients had ≥90% decrease in VPB frequency (Fig. 2). In 27 patients encainide was judged ineffective. Although paroxysms of VT persisted, the rate of the arrhythmia was significantly decreased from a mean of 202 to 142 beats/min; however, the mean length of each salvo was unaltered.

Thirty-five of the 51 patients (69%) who had repeat exercise testing responded to encainide. VPBs were reduced from a control of 225 per test to 26 during encainide therapy. In 31 of the responders, couplets as well

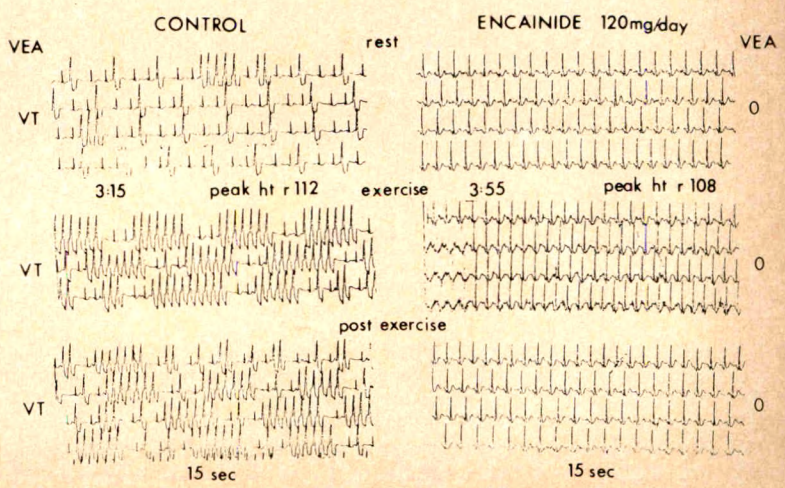

FIGURE 3. Electrocardiographic tracings from a patient who responded to encainide. During control studies frequent salvos of ventricular tachycardia (VT) were present during all hours of monitoring. Exercise testing increased the frequency of VT as well as length of the salvo. After 4 days of encainide therapy, ventricular arrhythmia was entirely abolished. VEA = ventricular ectopic activity.

as 4B arrhythmia were abolished. In the 35 responders the mean frequency of couplets was 21 per test in the control study and 0.3 during encainide therapy.

Overall, 34 patients (54%) responded to encainide when evaluated by both monitoring and exercise testing (Fig. 3). The mean dose in the responders was 152 ± 64 mg/day and that in nonresponders was 129 ± 46 mg/day. This difference was not statistically significant. The serum blood level of encainide in responders and nonresponders was 116 and 119 ng/ml, respectively, whereas values of OD-methyl-encainide were 98 and 100 ng/ml, respectively. These concentrations were not significantly different. Widening of the QRS complex was observed in 9 patients, but this did not correlate with response or drug level. There was no correlation between the underlying heart disease, presenting arrhythmia and efficacy of encainide.

Electrophysiologic studies: One patient who underwent electrophysiologic testing with encainide developed severe adverse effects (nausea and vomiting) that necessitated discontinuation of the drug before evaluation. Of the remaining 16 patients, 7 (44%) responded to encainide (Fig. 4). Six patients had sustained VT that had been provoked during control studies, whereas 1 patient had nonsustained VT. In 9 patients the drug failed to prevent the provocation of arrhythmia, although the rate of the VT with encainide therapy was slowed (202 versus 170 beats/min). The mean dose of the drug in responders and nonresponders was comparable (167 versus 179 mg/day). Overall, 41 of the 79 patients (52%) responded to encainide when evaluated with noninvasive or invasive studies.

Adverse effects: Toxicity occurred in 24 patients (30%) (Table II). This included severe nausea and vomiting, headaches, profound lethargy and tremors. One patient with pronounced QRS widening before receiving the drug developed third-degree atrioventricular block. In 18 patients (23%), arrhythmia was aggravated (Table II). The arrhythmia was aggravated in patients with and without heart disease. This occurred in 5 of the 10 patients who received >200 mg/day and in 13 of the remaining 70 patients (18.6%) receiving smaller doses of encainide. In 2 patients VF occurred for the first time; 1 patient had nonsustained VF (Fig. 5). Three patients who were free of advanced grades of ventricular ectopic activity and in whom VT occurred only with electrophysiologic testing had spontaneous salvos of VT at rest while taking encainide. Three patients who had nonsustained VT during control electrophysiologic testing had sustained VT with syncope provoked while receiving encainide. Cardioversion was required in each case. In these patients, VT was more easily provoked; that is, fewer extrastimuli were used compared with control testing. The remaining 9 patients who underwent noninvasive studies had sustained VT with encainide, although in control studies only short paroxysms of sustained VT occurred. In 7 of these patients, ambulatory monitoring while taking encainide showed a reduction of arrhythmia, but exercise provoked sustained VT that had not occurred with exercise. Cardioversion or another antiarrhythmic drug (lidocaine or procainamide administered intravenously) were required in each. The dose of drug and the blood levels were significantly higher for those exhibiting aggravation (that is, 191 and 178 ng/ml, respectively). The level of the OD-methyl-encainide metabolite was also higher than in patients in whom encainide was effective (307 ng/ml) ($p < 0.005$). Widening of the complex QRS did not predict aggravation of arrhythmia and occurred in only 5 of the 18 patients.

Long-term therapy: Twenty-seven patients were discharged on encainide. The type of heart disease in these patients was similar to that in the whole group. The basis for its selection included efficacy, absence of adverse effects and patient preference (Table III). Twenty-three patients continued therapy for an average of 21 months (range 12 to 44). Persistent and increasing lethargy compelled discontinuation of encainide in 1 patient. Four patients died: 1 from progressive congestive heart failure after 13 months of therapy, and in 3 death was sudden. These 3 patients had a history of VT with syncope.

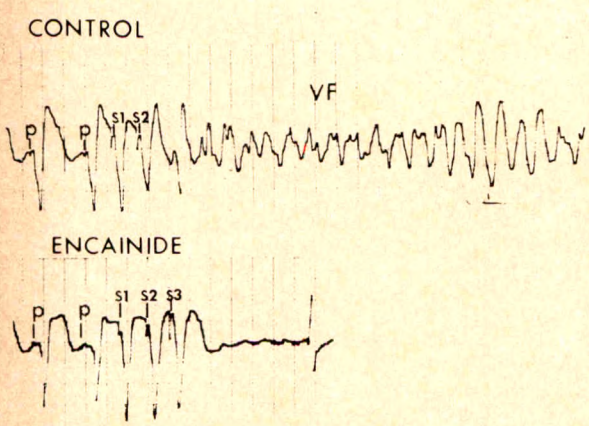

FIGURE 4. Electrocardiographic tracings from a patient who responded to encainide during invasive electrophysiologic testing. During control studies, 2 extrastimuli (S_1 and S_2) added during ventricular pacing (p) provoked ventricular fibrillation (VF). When the patient received encainide, as many as 3 extrastimuli (S_1, S_2 and S_3) failed to provoke repetitive responses.

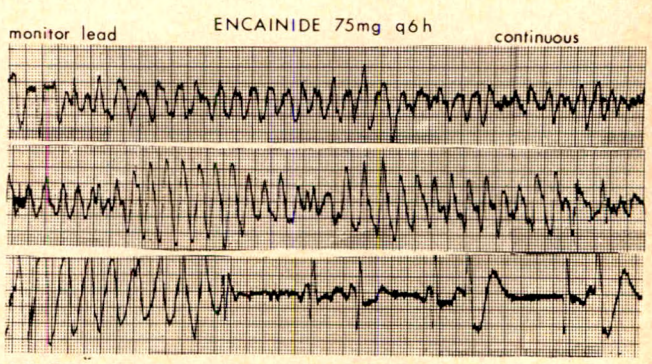

FIGURE 5. Aggravation of arrhythmia in a 30-year-old woman who had mitral valve prolapse and frequent ventricular premature beats with short salvos of uniformed ventricular tachycardia that were provoked during exercise testing. After 4 days of encainide therapy she complained of dizziness and had 4 syncopal episodes. Monitoring during this time demonstrated nonsustained ventricular fibrillation.

TABLE II Adverse Effects Observed in 24 of 80 Patients Treated With Encainide

Atrioventricular block	1		
Tremor	1

Discussion

Protecting the patient against a recurrence of malignant ventricular arrhythmia requires individualized therapy with antiarrhythmic drugs.[9] In the Seattle Heart Watch program, the recurrence rate of ventricular fibrillation was 26% during the first year of follow-up regardless of the antiarrhythmic therapy administered to two thirds of these patients.[15] However, therapy was empiric, without systematic drug evaluation. An effective medical program mandates ascertainment of drug efficacy.

Establishment of an effective treatment program requires the adherence to precise standards for assessing drug efficacy. Our criteria include complete abolition of grade 4B and 5 VPBs, ≥90% reduction in couplets, and ≥50% reduction in frequency of VPBs during both ambulatory monitoring and exercise stress testing. During electrophysiologic studies drug efficacy is defined as the inability to provoke multiple repetitive responses during both sinus rhythm and ventricular pacing. When patients are managed with antiarrhythmic drugs using these criteria, survival is improved.[12,14] This was demonstrated in 123 consecutive patients who frequently experienced recurring life-threatening ventricular arrhythmias.[14] Among 98 patients in whom the criteria for drug effectiveness were met, the annual incidence of sudden death was only 2.3%, compared with the 50% annual mortality rate in the 25 patients in whom control was not achieved. There were no clinical variables, including extent of left ventricular functional impairment, that distinguished the 2 groups.

Our success rate with encainide was 52%—less than that of Roden et al,[4] who reported nearly complete abolition of ventricular arrhythmia in 10 of 11 patients. Their patients had frequent VPBs, but had not experienced sustained life-threatening ventricular tachyarrhythmias. Furthermore, Roden et al excluded patients with angina pectoris or those who had congestive heart failure. Mason and Peters[5] reported a response rate similar to ours, with a 54% effectiveness among 35 patients treated with encainide for symptomatic VT. However, different criteria of efficacy were used. Mason and Peters adjudged the drug effective when symptomatic arrhythmia was prevented even if salvos of VT persisted. In contrast, we stipulated complete elimination of grade 4B or 5 VPBs during both ambulatory monitoring and maximal exercise stress testing.

Adverse effects: Antiarrhythmic drugs may worsen ventricular arrhythmias. Velebit et al[16] studied a large number of antiarrhythmic agents and found recorded aggravation of arrhythmia in 6 to 16% of drug studies. Mason and Peters[5] reported worsening of arrhythmia in 4 of 36 patients (11%) receiving encainide. In 1 patient the frequency of salvos of VT increased and in 3 VF occurred for the first time. Nicholson et al[7] observed an increase in arrhythmia during electrophysiologic study in 4 of 17 patients (23%). DiBianco et al[17] described the occurrence of sustained VT in 3 of 20 patients (15%) treated with encainide for chronic ventricular premature beats.

In our study 23% of patients treated with encainide had worsening of arrhythmia. However, this adverse effect was related to drug dosage. Thus, the incidence was 50% in patients who received >200 mg/day and 18.6% for those who received a smaller dose. That the dose was a critical factor is supported by the fact that blood levels of encainide and OD-methyl-encainide were significantly higher in patients who had an aggravation of arrhythmia than in those who were free of this effect. The extensive overlap in blood encainide values precludes their use for anticipating drug effect. Changes in electrocardiographic intervals were similar without predictive value of a toxic response. In a small series, Bren et al[18] reported that worsening of arrhythmia was associated with QT prolongation. In our experience no changes in either QRS width or QT-interval duration had predictive value.

In 7 patients worsening of arrhythmia occurred during exercise testing at a time when monitoring showed suppression of ventricular premature beats. Five of the 7 patients had received >200 mg/day of encainide. With such large doses, either the drug or its metabolites may excessively depress conduction velocity, prolong refractoriness and promote inhomogeneity in other electrophysiologic properties. These changes establish preconditions for arrhythmogenesis that results from exercise-promoted release of catecholamines.

The type and extent of underlying heart disease, the state of left ventricular function, and the presenting arrhythmia did not predict drug response. A systematic approach to drug testing such as that previously outlined[9,10] is essential to evaluate drug efficacy and reduce the incidence of adverse reactions during long-term therapy. Only 1 patient discontinued the drug because of an adverse effect during chronic maintenance.

We conclude that encainide is an effective agent for the treatment of malignant ventricular arrhythmias. However, there is a substantial risk for enhancement of arrhythmia that requires careful use of the drug. Recognition of the potential for worsening of arrhythmia, especially when doses exceed 200 mg/day, permits this drug to be used without substantial risk of serious injury. Response to encainide must be evaluated with both monitoring and exercise testing because aggravation of arrhythmia frequently occurs only during exercise. Its use should be reserved for patients with life-threatening ventricular arrhythmias refractory to conventional drugs.

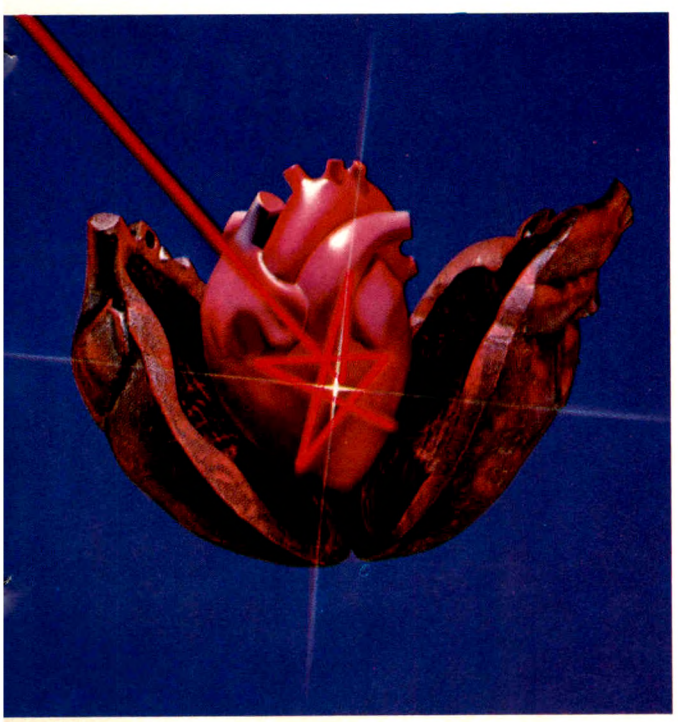
Heart failure makes
life more difficult

CAPOTEN®
(captopril tablets)
makes living
easier

SQUIBB

With the availability of CAPOTEN, heart failure† patients can enjoy an enhanced quality of life. Because, in patients who require more than digitalis and diuretics, CAPOTEN can improve their hemodynamic profile[1] and provide an opportunity to feel better.

- Eases principal heart failure symptoms[1]
- Restores patients' sense of well-being[1]
- Increases patients' capacity for exercise,[1] allowing them to participate more fully in the physical activities of everyday life



ACE* INHIBITOR

CAPOTEN®
(captopril tablets)

Can make the difference between merely existing and actively living

†CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

*Angiotensin Converting Enzyme

Please see brief summary of prescribing information on last pages of this advertisement.

ACE*INHIBITOR

CAPOTEN®
(captopril tablets)

CAPOTEN has been associated with the development of neutropenia/agranulocytosis (0.3% of 4,000 patients) or proteinuria (1.2% of 4,000 patients).† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.

The following precautionary guidelines are recommended for all patients receiving CAPOTEN:

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

*Angiotensin Converting Enzyme

†Please see brief summary of prescribing information on last pages of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

Reference: 1. Data on file, Squibb Institute for Medical Research.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension — Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.
Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.
WARNINGS: Proteinuria — Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis — Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension — Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTION: General: *Impaired Renal Function,* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.
Surgery/Anesthesia — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.
Drug Interactions: *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.

Agents Having Vasodilator Activity: In heart failure patients vasodilators should be administered with caution.

Agents Causing Renin Release — Captopril's effect will be augmented by

 (Continued on next page.)

ontinued from preceding page)

ıtihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity — The sympathetic nervous system ay be especially important in supporting blood pressure in patients receiving ıptopril alone or with diuretics. Beta-adrenergic blocking drugs add some rther antihypertensive effect to captopril, but the overall response is less an additive. Therefore, use agents affecting sympathetic activity (e.g., anglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium — Give potassium-sparing diuretics or otassium supplements only for documented hypokalemia, and then with aution, since they may lead to a significant increase of serum potassium.

rug/Laboratory Test Interaction: Captopril may cause a false-positive urine st for acetone.

arcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year udies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any vidence of carcinogenic potential. Studies in rats have revealed no impair- ient of fertility.

sage in Pregnancy: There are no adequate and well-controlled studies in regnant women. Embryocidal effects were observed in rabbits. Therefore, aptopril should be used during pregnancy only if the potential benefit utweighs the potential risk to the fetus.

ursing Mothers: Captopril is secreted in human milk. Exercise caution when dministering captopril to a nursing woman, and, in general, nursing should be terrupted.

ediatric Use: Safety and effectiveness in children have not been established though there is limited experience with use of captopril in children from 2 onths to 15 years of age. Dosage, on a weight basis, was comparable to that sed in adults. Captopril should be used in children only if other measures for ontrolling blood pressure have not been effective.

DVERSE REACTIONS: Reported incidences are based on clinical trials volving about 4000 patients.

Renal — One to 2 of 100 patients developed proteinuria (see WARNINGS). enal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 2 of 1000 patients.

Hematologic — Neutropenia/agranulocytosis occurred in about 0.3% of aptopril treated patients (see WARNINGS). Two of these patients developed epsis and died.

Dermatologic — Rash (usually mild, maculopapular, rarely urticarial), often ith pruritus and sometimes with fever and eosinophilia, in about 10 of 100 atients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in bout 2 of 100 patients. A reversible associated pemphigoid-like lesion, and hotosensitivity have also been reported. Angioedema of the face, mucous embranes of the mouth, or of the extremities in about 1 of 100 patients — eversible on discontinuance of captopril therapy. One case of laryngeal dema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular — Hypotension in about 2 of 100 patients. See WARNINGS (ypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypo- ension on initiation of captopril therapy. Tachycardia, chest pain, and alpitations each in about 1 of 100 patients. Angina pectoris, myocardial ıfarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 000 patients.

Dysgeusia — About 7 of 100 patients developed a diminution or loss of taste erception; taste impairment is reversible and usually self-limited even with ontinued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, omiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizzi- ess, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and pares- hesias reported in about 0.5 to 2% of patients but did not appear at increased requency compared to placebo or other treatments used in controlled trials.

ltered Laboratory Findings: Elevations of liver enzymes in a few patients lthough no causal relationship has been established. Rarely cholestatic aundice and hepatocellular injury with secondary cholestasis have been eported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In nstances of rapid reduction of longstanding or severely elevated blood ressure, the glomerular filtration rate may decrease transiently, also resulting n transient rises in serum creatinine and BUN. Small increases in serum otassium concentration frequently occur, especially in patients with renal mpairment (see PRECAUTIONS).

)VERDOSAGE: Primary concern in correction of hypotension. Volume xpansion with an I.V. infusion of normal saline is the treatment of choice for estoration of blood pressure. Captopril may be removed from the general irculation by hemodialysis.

)OSAGE AND ADMINISTRATION: CAPOTEN should be taken one hour efore meals. Dosage must be individualized; see DOSAGE AND ADMINIS- RATION section of package insert for detailed information regarding dosage n hypertension and in heart failure. Because CAPOTEN (captopril) is excreted rimarily by the kidneys, dosage adjustments are recommended for patients vith impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

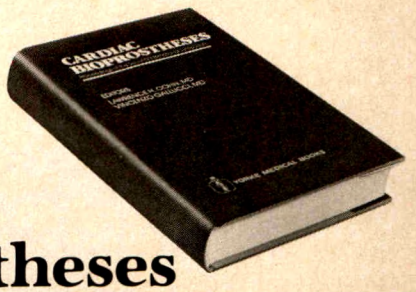
IOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, nd in UNIMATIC® unit-dose packs of 100 tablets.

SQUIBB®

NNOVATORS IN CARDIOVASCULAR MEDICINE

© 1983 E. R. Squibb & Sons, Inc. Princeton, N.J. 08540 523-505 Issued: May 1983

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bio-engineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

OXIMETRIX has invented

the smart catheter...

continuously answering the question : how well is oxygen delivery being managed to meet oxygen demand?

The OXIMETRIX P7110 Opticath® fiberoptic pulmonary artery catheter provides continuous real-time measurement of $S\bar{v}O_2$. Since $S\bar{v}O_2$ naturally reflects the balance between oxygen supply and demand, continuous measurement of $S\bar{v}O_2$ provides the continuously integrated net result of how well oxygen delivery variables (C.O. and SaO_2) are being managed or are compensating to meet O_2 demand.

This **third generation** PA catheter significantly enhances care of the high risk patient in two important ways:

☐ Early Warning Monitor

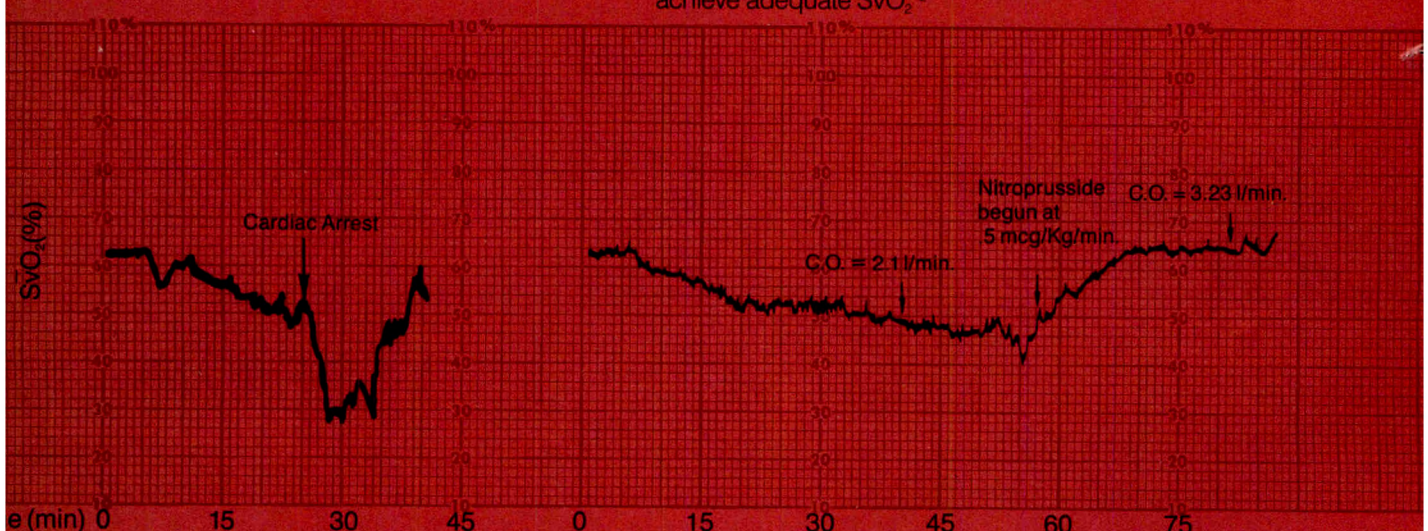
Often, changes in $S\bar{v}O_2$ reflecting deterioration in cardiorespiratory function occur prior to changes in other continuously monitored parameters.[3,4]

In this case, a gradual decline in $S\bar{v}O_2$ over 20 minutes heralded the onset of cardiac arrest (arrow) for which resuscitation was successful. Systolic blood pressure was stable (90–100mmHg) pre-arrest.[1]

☐ Patient Management

Clinical judgments can frequently be made at bedside that arterial oxygenation and oxygen consumption are constant. In these cases, changes in cardiac output are directly reflected in changes in $S\bar{v}O_2$.[1,2]

This postoperative patient with high systemic vascular resistance and low cardiac output required afterload reduction. Changes in cardiac output were directly reflected in changes of $S\bar{v}O_2$ and drug therapy was titrated to achieve adequate $S\bar{v}O_2$.[2]



1 Baele PI., McMichan JC., Marsh HM., and Southorn PA. "Continuous Monitoring of Mixed Venous Oxygen Saturation in Critically Ill Patients," **Anesthesia and Analgesia,** Vol. 61, No. 6, June 1982.

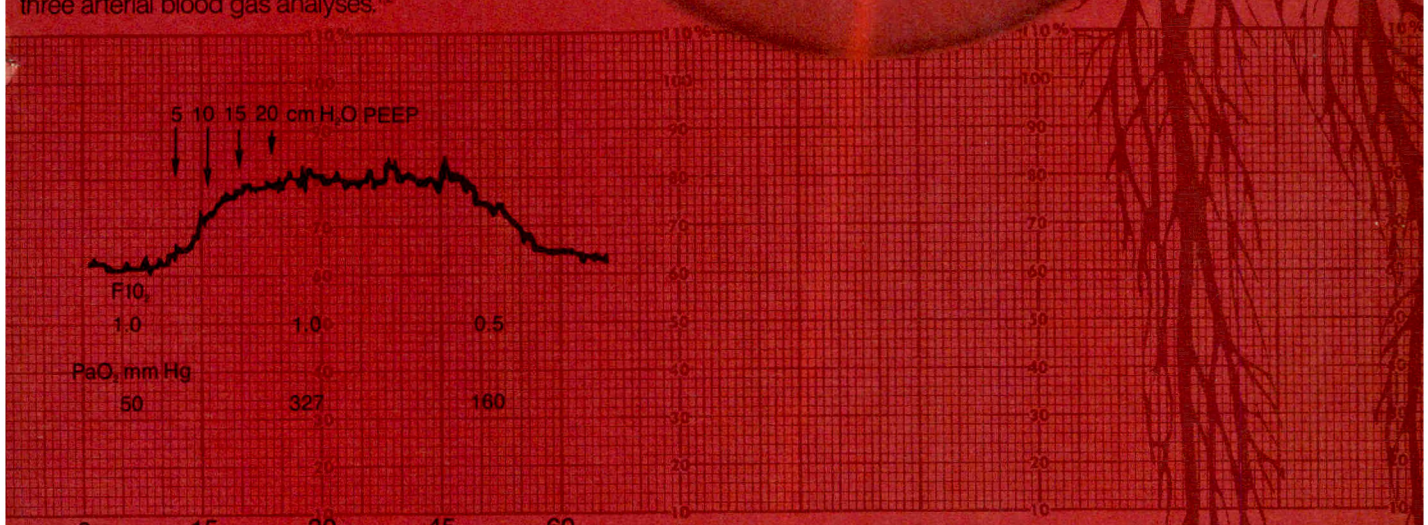
2 Schweiss J. (Ed). "Continuous Measurement of Blood Oxygen Saturation in the High Risk Patient," Vol. 1, (proceedings of a seminar held in conjunction with the Eleventh Annual Symposium of the Society of Critical Care Medicine), 1983.

3 Schmidt CR., Frank LP., Estafanous FG. "Utility of Continuous Pulmonary Artery Oximetry As An Early Warning Monitor in Cardiac Surgery Patients," paper presented at the 57th Congress of the International Anesthesia Research Society, New Orleans, March, 1983.

4 Watson C. "The PA Catheter As An Early Warning System," **Anesthesiology Review,** Vol. 10, No. 5, 1983.

Without continuous $S\bar{v}O_2$ monitoring, adjustment of PEEP and FIO_2 normally requires hours with numerous arterial blood gas analyses and cardiac output determinations.

In this case, PEEP was adjusted in 15 minutes and FIO_2 reduced within one hour with only three arterial blood gas analyses.[1,2]



Continuous Measurement of $S\bar{v}O_2$ with the P7110 Opticath® and the Shaw Catheter Oximetry System. Invented, developed and patented by OXIMETRIX, Inc.

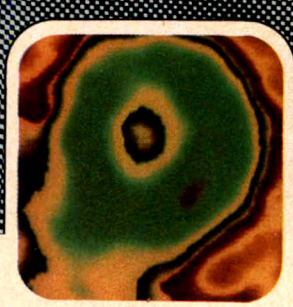
PRIORITIES IN TREATMENT OF ANXIOUS

Thallium scintiscan after exercise, showing marked anterior wall perfusion defect (arrow) before angioplasty.[1]



Postangioplasty thallium scintiscan showing no perfusion defect after peak exercise.[1]

FIRST THE BENEFITS OF PRIMARY MEASURES

Never before have physicians had so many resources for dealing effectively with cardiac disease. Now numerous cardiovascular medications are available—antianginal preparations, antihypertensives, diuretics, calcium antagonists, digitalis, quinidine, vasodilators. Besides these many agents, there are proven surgical procedures such as coronary bypass and valve replacement—and nonsurgical procedures such as angioplasty, which is fast becoming an accepted method of treating severe arterial stenoses.[1] The efficacy of angioplasty is illustrated in the above scintiscans. Yet, even with so many primary measures for improving the patient's cardiovascular status, secondary problems may adversely affect convalescence. One such problem may be excessive anxiety.[2]

SECOND THE BENEFITS OF ADJUNCTIVE ANTIANXIETY MEASURES

Anxiety in cardiac patients during recovery is a frequent response to symptoms such as chest pain, arrhythmias, breathlessness and weakness.[3] Often, anxiety can be allayed by supportive measures, such as encouraging the patient to express his fears openly, offering reassuring explanations for postcoronary symptoms and, when necessary, prescribing antianxiety medication.[3] For valid reasons, the medication often chosen is Valium® (diazepam/Roche). Its record of efficacy and safety is universally acknowledged. Little or no cardiotoxicity has been reported. Also, Valium is used with most primary cardiac medications. As with all CNS-acting agents, patients should be cautioned against drinking alcohol and against engaging in activities requiring complete mental alertness. Used judiciously, Valium can be a valuable adjunct to rehabilitative measures and can help the cardiac patient employ his own coping devices to good effect.

VALIUM®

diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

Second to none in pharmacotherapy of anxiety

Please see next page for summary of complete product information.

ROCHE®

VALIUM® (IV)
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety. Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic. Symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not as sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.
Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
The clearance of Valium and certain other benzodiazepines can be delayed in association with Tagamet (cimetidine) administration. The clinical significance of this is unclear.
Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.
Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. or q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
How Supplied: For oral administration, Valium scored tablets—2 mg, white; 5 mg, yellow; 10 mg, blue—bottles of 100 and 500; Prescription Paks of 50, available in trays of 10. Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10.

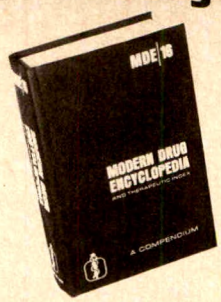
How thorough and unbiased is your drug reference?



If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information.
A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT... useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis.

Induction of Clinical Ventricular Tachycardia Using Programmed Stimulation: Value of Third and Fourth Extrastimuli

DAVID E. MANN, MD, JERRY C. LUCK, MD, JERRY C. GRIFFIN, MD, JOHN M. HERRE, MD, MARIAN C. LIMACHER, MD, SHARON A. MAGRO, PAC, NANCY W. ROBERTSON, CVNS, and CHRISTOPHER R. C. WYNDHAM, MD

Initiation of ventricular tachycardia (VT) by right ventricular extrastimulation was analyzed in 142 consecutive patients, 53 with electrocardiographically documented episodes of spontaneous VT or ventricular fibrillation (VF) and 68 with no spontaneous VT or VF; 21 patients with a history of sudden death but no documented arrhythmia were excluded from further analysis. All patients received 1 to 4 extrastimuli (S_2, S_3, S_4 and S_5) during pacing at fixed cycle lengths of 600 or 500 msec at 1 or 2 right ventricular sites. Clinical VT was reproduced by extrastimulation in 28 of 43 patients (65%) with sustained VT and in 0 of 10 patients with nonsustained VT. Clinical VT was induced by S_2 or S_3 in 16 patients and by S_4 or S_5 in 12 patients. Ventricular burst pacing reproduced clinical VT in 3 other patients. Nonclinical VT, which was most often polymorphic and nonsustained, was induced in 24 of 121 patients (20%), in 11 by S_2 or S_3 and in 13 by S_4 or S_5. Ventricular burst pacing induced nonclinical VT in 4 other patients.

In patients with spontaneous sustained VT, the use of S_4 and S_5 in the right ventricle increases the yield of inducible clinical VT compared with use of S_2 and S_3 alone, but at a cost of increased induction of nonclinical VT. Frequent induction of nonclinical VT limits the interpretation of the results of such stimulation in patients without previously documented VT.

(Am J Cardiol 1983;52:501–506)

Initiation of ventricular tachycardia (VT) by programmed stimulation has been used to plan effective therapy in patients with spontaneous episodes of VT.[1–5] However, to institute appropriate drug, pacemaker or surgical treatment, it is probably important that induced VT have the same mechanism as the spontaneous VT. This identity is manifested by similar morphology and cycle length of induced and spontaneous VT.

Most studies on the induction of VT using programmed stimulation have used up to 2 extrastimuli during multiple drive cycle lengths and at multiple right and left ventricular sites as well as short bursts of rapid ventricular pacing.[2–9] To increase the yield of inducible VT without resorting to left ventricular stimulation, we used third and fourth extrastimuli in the right ventricle. This report reviews our experience with this technique.

From the Cardiology Division, Methodist Hospital, Baylor College of Medicine, and the Veterans Administration Medical Center, Houston, Texas. Manuscript received March 3, 1983; revised manuscript received May 24, 1983, accepted May 25, 1983.

Methods

Patients: The hospital records and electrophysiologic recordings of 142 consecutive patients who underwent ventricular extrastimulation with at least 1 extrastimulus from July 1980 to June 1982 were reviewed. All available records were obtained for each patient, and every attempt was made to obtain electrocardiographic documentation of any episodes of spontaneous VT or ventricular fibrillation (VF). Patients were divided into 2 groups. Group I consisted of 53 patients (44 men and 9 women, mean age 57 ± 11 years) who had ≥1 spontaneous episode of VT or VF documented by electrocardiography before electrophysiologic study (including 12-lead electrocardiography, ambulatory or exercise electrocardiography or a single-channel rhythm strip). Group II consisted of 68 patients (35 men and 33 women, mean age 46 ± 17 years) with no history of VT, VF or sudden cardiac death. Twenty-one patients with a history of sudden cardiac death but without electrocardiographic documentation of the causative arrhythmia were excluded from further analysis because the electrocardiographic morphology and cycle length

TABLE I Clinical Data

	Group I (n = 53)	Group II (n = 68)
Cardiac diagnosis		
CAD	38	11
CM	8	8
VHD	3	12
Cardiac tumor	2	0
No OHD	2	37
Indication for study		
Sustained VT	40	0
Nonsustained VT	10	0
VF	3	0
PSVT, AF, AFL	0	32
Conduction disease	0	10
Syncope, palpitations	0	26

AF = atrial fibrillation; AFL = atrial flutter; CAD = coronary artery disease; CM = cardiomyopathy; OHD = organic heart disease; PSVT = paroxysmal supraventricular tachycardia; VF = ventricular fibrillation; VHD = valvular heart disease (including mitral valve prolapse); VT = ventricular tachycardia.

TABLE II Induction of Clinical and Nonclinical Ventricular Tachycardia With Each Extrastimulus

	Group I			Group II	
Extrastimulus	n	CVT	NCVT	n	NCVT
S_2	53	8	1	68	1
S_3	46	8	7	26	2
S_4	31	5	7	18	4
S_5	16	7	1	12	1

n = number of patients who received each extrastimulus; CVT = number of patients in whom clinical ventricular tachycardia was induced with each extrastimulus; NCVT = number of patients in whom nonclinical VT was induced with each extrastimulus.

of the arrhythmia could not be established. The cardiac diagnoses in each group determined by history, physical examination, noninvasive testing and cardiac catheterization are listed in Table I. Coronary artery disease was the most frequent diagnosis in Group I, occurring in 38 patients (22 of whom were diagnosed by coronary arteriography); 34 patients had electrocardiographically documented remote (>1 month) myocardial infarction and evidence of regional wall motion abnormalities on 2-dimensional echocardiography or nuclear-gated wall motion study. Thirty-seven of the 68 patients in Group II had no heart disease. The most frequent reason for undergoing electrophysiologic study in Group II was supraventricular tachyarrhythmias (32 patients).

Definitions: The following definitions were used.

Nonsustained VT: VT of ≥6 beats that terminated spontaneously in <1 minute.

Sustained VT: VT that lasted >1 minute or required termination because of hemodynamic compromise. VF is grouped with sustained VT unless stated otherwise.

Induced VT: VT initiated by either extrastimulation or ventricular burst pacing at least once during electrophysiologic study.

Clinical VT: Spontaneous VT documented before electrophysiologic study. Induced VT was considered to be clinical VT if it was morphologically similar to spontaneous VT in every electrocardiographic lead recorded during electrophysiologic study (in general, similar morphology in lead V_1 and frontal-plane QRS axis within 45°), and the cycle length was similar to spontaneous VT (within 10% of spontaneous VT cycle length). The latter criterion was not used if spontaneous VT was documented only while the patient was taking class I antiarrhythmic drugs.

Nonclinical VT: Induced VT not identical, by the above criteria, to spontaneous VT.

S_1S_1: Basic paced cycle length.

S_2, S_3, S_4, S_5: First, second, third and fourth extrastimuli introduced during ventricular pacing at constant cycle length.

V_1V_2, V_2V_3, V_3V_4, V_4V_5: The coupling interval (in milliseconds) between the appropriate ventricular electrograms, measured at the first high-frequency crossing of the baseline.

Electrophysiologic studies: Electrophysiologic studies were performed in the postabsorptive, nonsedated state. Intracardiac electrode catheters were inserted through the femoral, brachial or subclavian veins. Programmed stimulation was performed using a digital stimulator (Bloom Associates, Ltd.) that delivered rectangular pulses of 2 msec duration at twice diastolic threshold. Surface leads I, II, III and V_1, and intracardiac electrograms were simultaneously recorded on light-sensitive paper at 100 mm/s paper speed (Electronics for Medicine VR-16 recorder).

Extrastimulation was performed in all patients at 1 or 2 right ventricular sites, either the right ventricular apex or septum. Two sites were used in 18 Group I patients (34%) and 18 Group II patients (26%) (not statistically significant [NS]). Left ventricular stimulation was not performed. Extrastimulation included introduction of S_2 through S_5 after 8 beats of ventricular pacing at a basic drive cycle length of 500 msec in 45 Group I and 39 Group II patients (NS); otherwise, 600 msec was used. Each successive extrastimulus was introduced decrementally until refractoriness was reached, then fixed at 20 ms beyond refractoriness while the next extrastimulus was introduced. In Group I patients, extrastimulation was continued until VT was induced or the protocol was completed. In Group II patients, who had no history of VT, fewer patients received the complete protocol. Extrastimulation using S_4 or S_5 was performed in 31 Group I (58%) and 18 Group II patients (26%) ($p < 0.001$). Ventricular burst pacing, consisting of 8 to 12 beats at decreasing cycle lengths down to 2:1 pacing non-

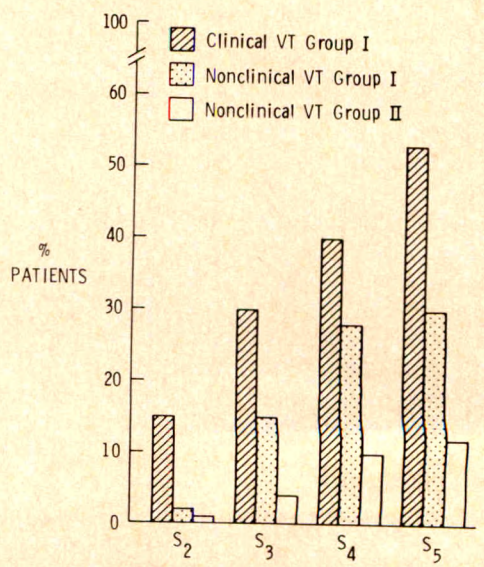

FIGURE 1. The cumulative yield of induced ventricular tachycardia (VT) (percentage of patients in each group with induced VT) with each added extrastimulus. With each additional extrastimulus, the rate of induction of clinical and nonclinical VT is increased in both groups.

capture, was then performed. Ventricular burst pacing was performed in 45 Group I (85%) and 64 Group II patients (94%) (NS). The minimum cycle length of ventricular burst pacing was <250 msec in 26 Group I (49%) and 37 Group II patients (54%) and 300 to 250 msec in the rest.

Induced VT was classified as clinical or nonclinical by the above definitions. The stimulation protocols that first initiated clinical and nonclinical VT in each patient were analyzed. The minimum attainable coupling intervals of the ventricular electrograms between each successive extrastimulus were measured.

Electrophysiologic studies were performed at least 48 hours after antiarrhythmic drugs had been discontinued. In patients with multiple studies in the drug-free state, only the first such was analyzed. However, in 11 of 14 patients whose spontaneous arrhythmia had only occurred while on a class I antiarrhythmic drug (procainamide, quinidine or disopyramide),[10] and who had no inducible VT in the control state, programmed stimulation was repeated after administration of intravenous procainamide (20 mg/kg) or, in 2 cases, on oral quinidine or disopyramide.

Statistical analysis: Numerical data were tested for significance by paired and unpaired t tests and by chi-square analysis. Values are given as mean ± standard deviation.

Results

Characteristics of spontaneous ventricular tachycardia: The most severe documented arrhythmia in Group I was VF in 3 patients, sustained VT in 40 patients and nonsustained VT in 10 patients. VF was documented by single-channel rhythm strips in all 3 patients. Sustained VT was documented by a 12-lead electrocardiogram in 30 patients, by a single-channel rhythm strip in 7 and by multiple-lead ambulatory or exercise electrocardiogram in 3. Nonsustained VT was documented by multiple-lead ambulatory or exercise electrocardiography in all 10 patients. Multiple distinct morphologies of VT were documented in 14 of 53 Group I patients (26%). Seventy-one different morphologies were documented in all 53 patients.

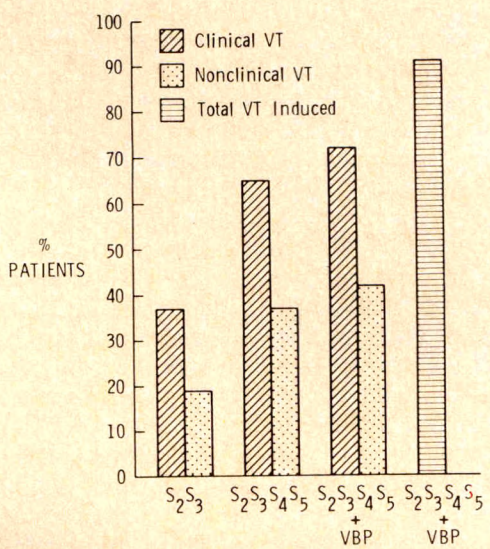

FIGURE 2. The cumulative yield of induced clinical and nonclinical ventricular tachycardia (VT) using progressively more "aggressive" modes of stimulation in 43 patients with a history of spontaneous sustained VT. Use of S_2S_3 alone, $S_2S_3S_4S_5$ and $S_2S_3S_4S_5$ plus ventricular burst pacing (VBP) are compared. The bar farthest to the right represents overall VT induction, ignoring the distinction between clinical and nonclinical VT.

Ventricular tachycardia induction: *Clinical VT:* VT morphologically similar to spontaneous VT was induced in 31 of 53 Group I patients (58%). Clinical VT was only induced in patients with the sustained form spontaneously (31 of 43 [72%]). Induced clinical VT was sustained in 26 patients and nonsustained, though of similar morphology and cycle length to spontaneous VT, in 5 patients. Clinical VT was not initiated in any patient whose spontaneous arrhythmia was nonsustained (0 of 10 patients). Considering only patients with spontaneous sustained VT (or VF), clinical VT was induced in 28 of 43 (65%) by extrastimulation, and in 3 of 43 (7%) by ventricular burst pacing alone.

Nonclinical VT: Nonclinical VT was induced in 28 of the 121 patients (23%). In Group I nonclinical VT was induced in 19 of 53 patients (36%), and was nonsustained in 11 and sustained in 8. In Group II nonclinical VT was induced in 9 of 68 patients (13%), and was nonsustained in 7 and sustained in 2. Nonclinical VT was induced in 24 of the 121 patients (20%) by extrastimulation and in 4 (3%) by ventricular burst pacing.

Comparison of modes of stimulation: Table II lists the number of patients in whom clinical and nonclinical VTs were induced with each extrastimulus. In Figure 1, these data are depicted graphically as the cumulative percentage of patients with VT induced after each extrastimulus was added. With each additional extrastimulus there is an increasing yield of induced clinical and nonclinical VT in both patient groups.

Figure 2 depicts VT induction in Group I patients with sustained spontaneous VT. Clinical VT was induced by S_2 or S_3 in 37% and nonclinical VT in 19% of these patients. With the addition of S_4 and S_5, clinical VT was induced in 65% and nonclinical VT in 37%. With the addition of ventricular burst pacing to extrastimulation, clinical VT was induced in 72% and nonclinical VT in 44%. The final bar in Figure 2 ignores the distinction between clinical and nonclinical VT and represents all induced episodes of VT. Thus, VT was induced in 91% of patients with the sustained arrhythmia spontaneously, using up to 4 extrastimuli and ventricular burst pacing in the right ventricle alone. Had S_4 and S_5 not been used, VT would have been inducible in only 65% of them from the right ventricle.

Drug-induced VT: In patients with spontaneous sustained VT, the spontaneous arrhythmia was documented on class I antiarrhythmic drugs in 23 of 43 patients (53%). Of these 23, clinical VT was induced in 12 (52%), and in 9 patients it was inducible in the drug-free state. Of the 14 patients in which VT could not be induced in the drug-free state, 11 were given a class I agent as described above and retested. Of these 11, in only 3 (27%) could VT then be induced.

Characteristics of induced ventricular tachycardia: Figure 3 is a comparison of the mean cycle lengths of clinical VT (spontaneous versus induced) and nonclinical VT in Groups I and II. As expected from the definition of clinical VT, there was no significant difference between the mean cycle length of spontaneous

TABLE III Morphologic Characteristics of Nonclinical Ventricular Tachycardia

NCVT Morphology	Group I	Group II	Total
Polymorphic nonsustained	6	6	12
Unimorphic sustained	6	2	8
Unimorphic nonsustained	5	1	6
Ventricular fibrillation	2	0	2
Totals	19	9	28

NCVT = nonclinical ventricular tachycardia.

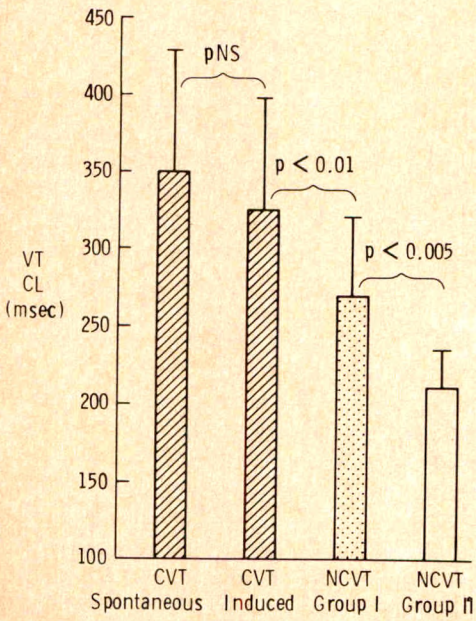

FIGURE 3. The mean cycle lengths (CL) of spontaneous ventricular tachycardia (VT) and induced clinical VT (CVT), as well as the mean CLs of induced nonclinical VT (NCVT) in both groups. NS = not significant.

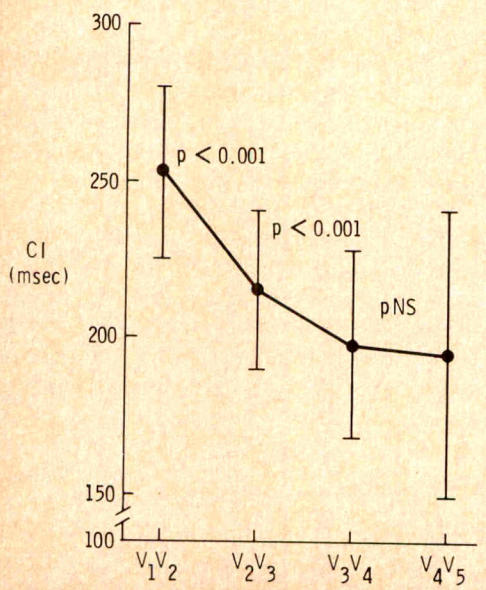

FIGURE 4. The mean minimum coupling intervals (CI) achievable by each pair of extrastimuli in 24 patients in whom all 4 extrastimuli were used and attained refractoriness. NS = not significant.

VT and induced clinical VT in group I (349.7 ± 78.5 versus 325.2 ± 73.4 msec, NS). Nonclinical VT in Group I patients had a significantly shorter mean cycle length than clinical VT (325.2 ± 73.4 versus 270.7 ± 51.3 msec, $p < 0.01$). Nonclinical VT in Group II had a still shorter mean cycle length than nonclinical VT in Group I (270.7 ± 51.3 versus 212.3 ± 23.4 msec, $p < 0.005$).

Induced clinical VT was most often unimorphic and sustained (26 patients). Induced clinical VT was unimorphic and nonsustained in 1 patient and polymorphic and nonsustained in 3. Of the 2 patients with spontaneous VF, 1 had no inducible VT or VF and 1 had what appeared morphologically to be induced VF (characterized by disorganized electrical activity in the intracardiac ventricular leads) that terminated spontaneously.

The morphologic characteristics of nonclinical VT are listed in Table III. The most common morphology was polymorphic and nonsustained; however, unimorphic forms occurred in both groups, although rarely (3 patients) in Group II. VF was induced in 2 patients in Group I in whom it had never occurred spontaneously and in no patients in Group II. Nonclinical VF was induced by S_4 in one case and by ventricular burst pacing at a cycle length of 230 msec in the other.

Analysis of minimum coupling intervals: The minimum achievable coupling intervals between the ventricular electrograms produced by S_2 through S_5 were averaged in 24 patients in whom all four extrastimuli were given and in whom each extrastimulus attained refractoriness. The results are illustrated in Figure 4. The mean coupling intervals decreased with each pair of extrastimuli, but in a decremental fashion (V_1V_2 253.1 ± 27.6 versus V_2V_3 215.4 ± 25.7, $p < 0.001$; V_2V_3 versus V_3V_4 198.3 ± 30.3, $p < 0.001$; V_3V_4 versus V_4V_5 194.6 ± 46.2 msec, NS).

Discussion

Programmed stimulation has been used in the electrophysiology laboratory to initiate VT in patients who have this arrhythmia spontaneously.[1–9] Drug treatment based on the results of acute drug testing using programmed stimulation is superior to empiric therapy in patients with inducible VT.[1–5] The ability to induce VT is crucial for successful surgical treatment of VT[11] and to test the reliability and safety of implanted tachycardia-terminating pacemakers.[12] More recently, programmed stimulation has been used in patients without a definite history of VT as a means to identify causative arrhythmias in patients with syncope[13,14] and to identify a group at high risk for subsequent sudden death after acute myocardial infarction.[15,16]

Pacing protocols used for induction of VT vary from laboratory to laboratory, making it difficult to compare the results of previous studies on the inducibility of VT. There is considerable variation in the number of extrastimuli used, the basic drive cycle lengths used and the sites of stimulation.[1–9] Changes in any of these factors may mean the difference between inducibility and noninducibility of VT. In a previous study using a protocol that included ≤2 extrastimuli and ventricular burst pacing at both right and left ventricular sites, VT was not inducible in 19% of patients with spontaneous

VT and was inducible from the left ventricle alone in 12%.[6] In a more recent, prospective study, again limited to 2 extrastimuli but without left ventricular stimulation, VT was induced in 71% of patients with spontaneous sustained VT and in 56% of patients with nonsustained VT.[7] Because left ventricular stimulation may increase the risk of electrophysiologic study by adding the risks of arterial catheterization and systemic embolism, and because chronic study of antiarrhythmic drugs is impractical in patients in whom VT is only inducible from the left ventricle, we used additional extrastimuli (S_4 and S_5) in the right ventricle in an attempt to increase the yield of inducible VT without necessitating left ventricular stimulation. In doing so, we have attempted to determine if induced VT matches spontaneous VT in morphology and cycle length, as it has been suggested that use of more than two extrastimuli increases the induction of nonclinical VT.[17]

In patients with spontaneous sustained VT, use of S_4 and S_5 increased the percentage of patients in whom clinical VT was induced from 37 to 65% over using S_2 and S_3 alone, but at a cost of increased induction of nonclinical VT (from 19 to 37%). Ventricular burst pacing further increased the induction of clinical and nonclinical VT to 72% and 44% of these patients. In our 10 patients who were studied for episodes of nonsustained VT, clinical VT was not inducible using our protocol. This contrasts with previous studies that, although showing lower inducibility of nonsustained VT as compared with sustained VT, still report inducibility in 56 to 62% of patients.[6,7] However, Denes et al[8] reported that clinical VT was not inducible in 6 patients studied with spontaneous nonsustained VT,[8] and Wellens et al[9] found that it could be induced in only only 1 of 15 patients with nonsustained VT. This variation in reported inducibility of nonsustained VT may, in part, be explained by differences in the definition of nonsustained VT. We defined nonsustained VT as 6 or more consecutive ventricular beats in order to prevent the interpretation of the repetitive ventricular response, which commonly occurs in normal and abnormal patients during programmed stimulation as nonsustained VT.[18]

The significance of nonclinical VT induction by programmed stimulation is uncertain. Reddy and Sartini[19] found a 50% incidence of nonclinical VT induction in patients with spontaneous sustained VT, and Mason and Winkle[3] found that nonclinical VT was induced in 16% of such patients. We found that nonclinical VT tends to be of significantly shorter cycle length than spontaneous VT, and is usually a nonsustained polymorphic arrhythmia. Nonclinical VT was more commonly induced in Group I patients, and this may, in part, reflect the more aggressive stimulation protocol used in these patients. However, more episodes of nonclinical VT tended to be unimorphic, sustained and of longer cycle length in Group I than Group II patients. It may be that nonclinical VT actually represented clinical VT that had not previously been documented, or different ventricular activation by the same reentrant circuit, a phenomenon shown to occur by endocardial catheter mapping.[20] Whether nonclinical VT in general is a marker of electrical instability, and thus a predictor of subsequent clinical events, or merely an artifact of the technique of programmed stimulation remains to be determined.

We analyzed the minimum attainable coupling intervals in our patients. Other than atrioventricular nodal refractory periods, cardiac refractory periods normally shorten as the cycle length of pacing shortens.[21] Introducing multiple extrastimuli during ventricular pacing at a fixed cycle length may be used to achieve shorter coupling intervals than those attainable by using single extrastimuli or ventricular burst pacing alone. In patients with VT originating from the left ventricle, critically short coupling intervals required for initiation of reentry may not be achievable by using only double extrastimuli in the right ventricle, presumably because of conduction delay between the site of pacing and the reentrant circuit. In such cases pacing closer to the reentrant circuit (that is, in the left ventricle) or use of more extrastimuli in the right ventricle might then induce VT.[17] Shorter coupling intervals are achievable by using S_4 and S_5 than by S_2 or S_3; however, there is no difference between the minimum V_3V_4 and V_4V_5 intervals. This suggests that there may be a limit to the degree that refractoriness may be shortened by added extrastimuli. However, there is yet a greater yield of induced VT with S_5 than with S_4, suggesting that critical shortening of local refractoriness at the pacing site is not the only factor involved.

Limitations of the study: The present study is retrospective, and may underestimate the inducibility of both clinical and nonclinical VT because of failure to complete the protocol and variations in the number of ventricular pacing sites used and the drive cycle lengths used. This is especially applicable to the Group II patients, in whom it was difficult to perform aggressive ventricular stimulation because of the possibility of inducing life-threatening arrhythmias of questionable clinical significance. Future prospective studies should not only address more stringently the issue of inducibility of nonclinical VT in patients without known spontaneous VT, but also should carefully compare the value of using multiple sites, different drive cycle lengths, and low versus high currents of stimulation. How the use of S_4 and S_5 will affect serial drug testing needs to be determined. Swerdlow et al[22] found that in patients in whom VT is induced with S_3 or less in the control state, use of S_4 during drug testing may be associated with a high drug failure rate, which may be spurious. Long-term follow-up of patients with induced nonclinical VT is needed to determine how often such morphologies of VT do subsequently occur spontaneously.

Hemodynamic Effects of Encainide in Patients With Ventricular Arrhythmia and Poor Ventricular Function

MAGDI H. SAMI, MD, VILMA A. DERBEKYAN, MD, and ROBERT LISBONA, MD

Gated cardiac scanning was used to evaluate the hemodynamic effects of encainide in 19 patients (1 woman) with complex ventricular arrhythmia and depressed left ventricular (LV) function (ejection fraction <45%). Patients were 36 to 80 years old (average 61). All were candidates for long-term encainide therapy after having failed with currently available antiarrhythmics. Sixty-three percent had congestive heart failure before they received encainide. All were evaluated in the hospital before encainide therapy by a gated cardiac scan performed at least 3 days after discontinuing all antiarrhythmic drugs. Patients received oral encainide in doses of 75 to 200 mg. Gated cardiac scans were repeated 1 to 2 weeks later when an 80% reduction in frequency of premature ventricular complexes was observed on a 24-hour Holter recording. No patient had worsening of congestive heart failure during encainide therapy. Encainide did not significantly affect ejection fraction, which averaged 22 ± 10% before and 25 ± 14% (SD) after encainide (difference not significant [NS]). Other hemodynamic variables, including heart rate, blood pressure, stroke volume and end-diastolic volume, remained unchanged during encainide therapy. Digoxin blood levels in 10 patients averaged 1.04 ± 0.43 before and 1.22 ± 0.47 mg/ml (NS) during encainide therapy. Thus, encainide given orally in clinically effective doses does not appear to have significant hemodynamic effects in patients with ventricular arrhythmia and depressed LV function. (Am J Cardiol 1983;52:507–511)

Currently available oral antiarrhythmics have negative inotropic effects.[1–5] Although this may be of little consequence in patients with normal ventricular function, patients with depressed ventricular function may experience worsening of symptoms or may develop congestive heart failure when given these drugs on a long-term basis.[4,5] Newly developed antiarrhythmics should therefore be evaluated for their hemodynamic effects before they are used in long-term trials. Encainide is a new benzanilide derivative with demonstrated antiarrhythmic efficacy that has been well tolerated in many clinical trials.[6–10] However, little information is available about its long-term hemodynamic effects, especially in patients with depressed left ventricular (LV) function.[10] We used gated cardiac blood pool imaging to evaluate the effects of encainide on LV function in patients with ventricular arrhythmia and depressed ejection fraction (EF).

From the Departments of Cardiology and Nuclear Medicine, Royal Victoria Hospital and McGill University, Montreal, Canada. This study was supported in part by a grant-in-aid from Bristol Myers Company International Division, New York, New York.

Materials and Methods

The subjects of this study are a subgroup of patients with complex and symptomatic ventricular arrhythmia who were considered for encainide therapy because of failure to respond to other antiarrhythmic drugs. Patients were selected for this study if they satisfied the following criteria: they had an EF <45% on a gated cardiac scan; they remained in a monitored cardiac unit with antiarrhythmics for 3 days before baseline study; those with congestive heart failure were on unchanged doses of digoxin and diuretics for at least 4 weeks before baseline evaluation and during the entire period of the study; and they did not have second- or third-degree heart block or a QRS duration >0.14 second. (One patient only had complete right bundle branch block with QRS of 0.12 second.)

Of the 23 patients who satisfied the above criteria, 4 were excluded before completion of the study, 3 because of technical difficulties with gated scanning and 1 because of new-onset sustained ventricular tachycardia 1 day after starting encainide. Table I shows the clinical features of the 19 patients participating in the study. Sixteen had coronary artery disease and 3 had dilated cardiomyopathy. Thirteen had clinical signs of congestive heart failure of class III or IV severity. All had frequent premature ventricular beats, ranging from 20 to 1355 per hour (median 279). All had frequent pairs and 18 had ≥1 salvos of nonsustained ventricular tachycardia per 24 hours.

TABLE I Clinical Characteristics of the Study Patients

Age (yr)	Underlying Heart Disease	CHF	Encainide Dose (mg)	Concomitant Medications

* More than 3 months old.
† One to 3 months old.
CAD = coronary artery disease; CHF = congestive heart failure; DC = dilated cardiomyopathy; LV = left ventricular; MI = myocardial infarction; NYHA = New York Heart Association functional classification; + = present; 0 = absent.

Patients underwent a baseline evaluation that included clinical examination, with special attention to signs and symptoms of congestive heart failure; gated equilibrium cardiac blood pool scans; and routine hematologic and biochemistry laboratory work, resting 12-lead ECG and 24-hour Holter recordings. In addition, 10 ml of venous blood were obtained before their daily dose of digoxin to determine plasma concentrations.

All patients were then given encainide orally in doses of 25 mg every 8 hours. The dose was increased every 3 days to a maximum of 200 mg/day or until the patient demonstrated 80% reduction of the frequency of premature ventricular complexes on serial 24-hour Holter recordings without side effects. Encainide doses were 25 mg every 6 hours, 50 mg every 8 hours, or 50 mg every 6 hours.

Clinical examination, gated blood pool scanning, electrocardiography and routine hematology and biochemistry laboratory work were repeated 1 to 2 weeks after starting oral encainide therapy and digoxin and encainide blood levels were measured again.

Twenty-four-hour Holter recordings were performed using Oxford Medilog AM dual channel recorders 4-24/2. Analysis of the tapes was performed by a trained nurse using a Reynolds Pathfinder high-speed analyzer equipped with a printer interface module to allow printouts of the hourly totals of all QRS, all premature aberrant beats, pairs and salvos of ≥3 premature ventricular complexes. The pathfinder mode of action and its accuracy have been described.[11]

Digoxin plasma concentration was determined using a tritium radioimmunoassay method.[12] Plasma concentrations of encainide and its 2 common metabolites, O-demethyl encainide (ODE) and 3 methoxy ODE, were determined using high-pressure liquid chromatography.[13]

Data acquisition of the gated cardiac study was done with parallel low-energy collimation of a Picker mobile camera interfaced to an Informatek Simis 3 computer. Data were acquired in 16 equally timed frames of 64 × 64 matrices in the left anterior oblique position after in vivo labeling of the patient's red blood cells with 20 mCi of technetium-99m O_4^-. In the left anterior oblique position that showed the septum to best advantage, an additional 15° caudal tilt of the camera head was used to further facilitate atrioventricular separation. Arrhythmia filtering was obtained by establishing a tolerance window about the mean RR interval, rejecting cycles that varied more than 10% from the mean cycle length. Data were recorded over an imaging interval of 15 minutes or for a total accumulation of 5 million counts, depending on which limit was first reached. At the end of the acquisition, a 10-ml sample of the patient's blood was withdrawn and counted for 1 minute with the syringe in the direct contact with the collimator face.

For the analysis the data were normalized to ensure equal counts from each of the 16 frames. The raw data were smoothed with a 9-point filter and modified by threshold background subtraction. The second derivative approach helped determine the edges of the left ventricle.[14] The EF was calculated from the time-activity curve of the reconstituted cardiac cycle generated from a region of interest placed over the left ventricle by the operator. The stroke volume value in counts (LV end-diastolic counts LV end-systolic counts) was then converted into a volume equivalent in milliliters. This was done through division of the count stroke volume by the counts per milliliter of syringe blood. This syringe count value had previously been corrected by an attenuation factor to compensate for the different counting geometry and attenuation of the blood sample and the left ventricle.[15] Subsequently, end-diastolic volume was calculated from the EF and stroke volume.

To test the reproducibility of the LVEF, as measured by nuclear ventriculography in our laboratory, a sample of 20 patients (15 men, 4 women, average age 60 years) with heart disease underwent gated blood pool scanning twice within 20 minutes. Patients were allowed to walk around between the acquisitions and each acquisition was analyzed by a different operator. The 2 test results for EF were then assessed for their reproducibility using the product normal correlation coefficient, and the 95% two-tailed confidence intervals for this relationship were plotted as previously described.[16]

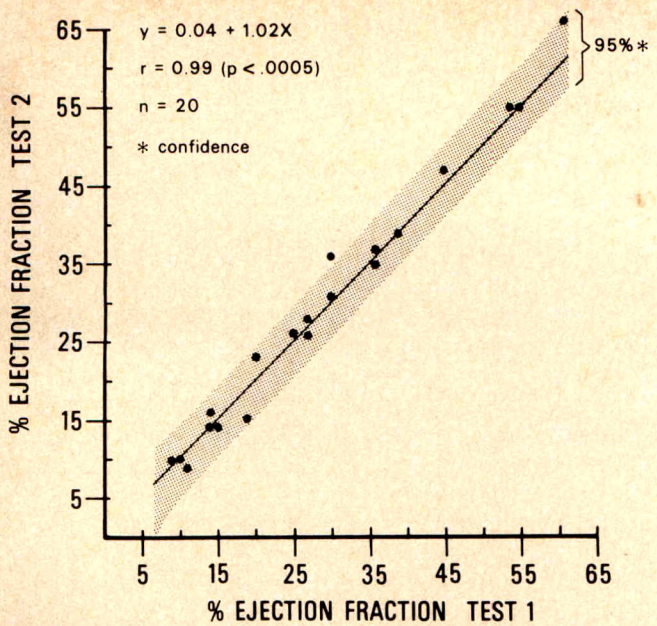

FIGURE 1. Linear regression analysis with 95%, 2-tailed confidence interval of variability for ejection fraction (EF). These measurements of EF were obtained from gated equilibrium blood pool scanning performed twice within 30 minutes.

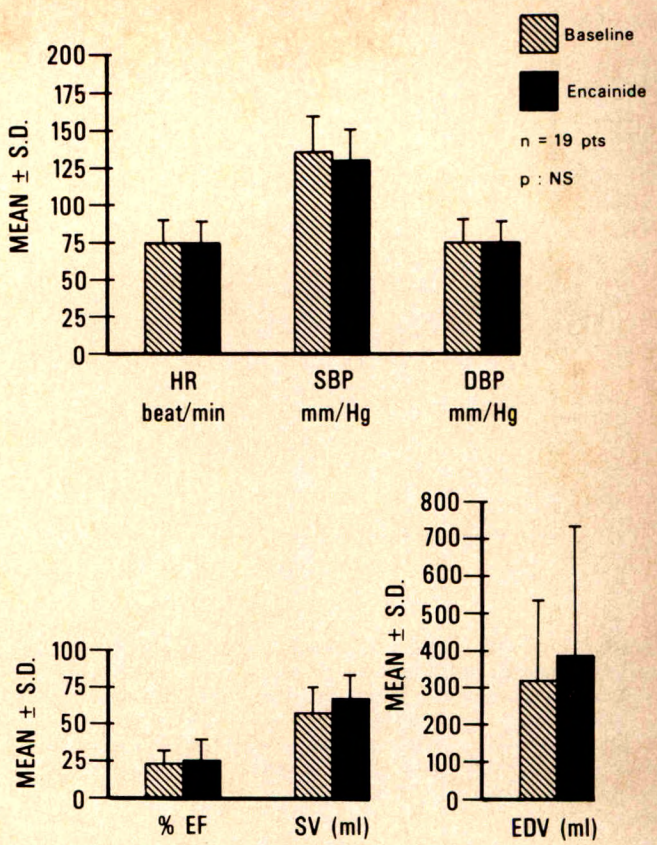

FIGURE 2. Means and standard deviations (SD) of hemodynamic indexes measured at basesline and during encainide therapy for 19 patients selected in the study. Statistical analysis using a paired *t* test did not show significant difference between measurements. DBP = diastolic blood pressure; EDV = end-diastolic volume; EF = ejection fraction; HR = heart rate; SBP = systolic blood pressure; SV = stroke volume.

Figure 1 shows the reproducibility of EF in our institution. The EF showed a high reproducibility (r = 0.99) and a relatively narrow 95% two-tailed confidence band. The maximum variation in EF between test 1 and test 2 was 5%.

Data obtained before and during treatment with encainide were analyzed by paired *t* tests to detect significant differences in heart rate, blood pressure, ejection fraction, stroke volume, end-diastolic volumes and digoxin plasma concentration.

Results

Hemodynamics: In the group as a whole, there was no significant change in heart rate, systolic or diastolic blood pressure, EF, stroke volume or end-diastolic volume before or after oral encainide (Fig. 2).

Individual values for EF at baseline and during oral encainide therapy were plotted on a graph representing the 95% two-tailed confidence band obtained as described in the Methods (Fig. 3). Most values fell within the 95% confidence band for variability, with only 4 patients showing a statistically significant increase and no patient showing a significant reduction in EF while receiving encainide.

Digoxin blood levels: Digoxin blood levels obtained in 10 patients before and 1 and 2 weeks after starting encainide therapy in various dosages were not significantly changed. The mean digoxin blood level at baseline was 1.04 ± 43 ng/ml (LSD) and at the end of 1 to 2 weeks of encainide, 1.22 ± 0.47 ng/ml (± SD) ($p > 0.25$).

Encainide plasma concentrations: The plasma concentrations and encainide and its 2 major metabolites after oral administration showed a marked interpatient variation, with little correlation of dosage: plasma concentrations of encainide ranged from 0 to 1110 ng/ml (mean 166), ODE from 0 to 665 ng/ml (mean 194) and 3 methoxy ODE from 0 to 916 ng/ml (mean 189).

Side effects: One patient who had been excluded 24 hours after starting encainide because of new-onset sustained ventricular tachycardia was later found not to have a detectable encainide or encainide metabolite in the plasma at the time of ventricular tachycardia. Another patient developed sustained ventricular tachycardia shortly after completing the 2-week period of study. Both were successfully resuscitated, but were never rechallenged with encainide.

Two patients demonstrated sinus pauses (≤2 seconds in duration) during encainide therapy, but remained asymptomatic. None of the the patients showed significant worsening of clinical signs or symptoms of congestive heart failure during the 2 weeks of the trial, although subtle changes may have been difficult to detect in class IV patients because of already severe symptoms and poor response to medication. Routine hematologic and biochemistry laboratory evaluation did not show any significant changes during administration of encainide.

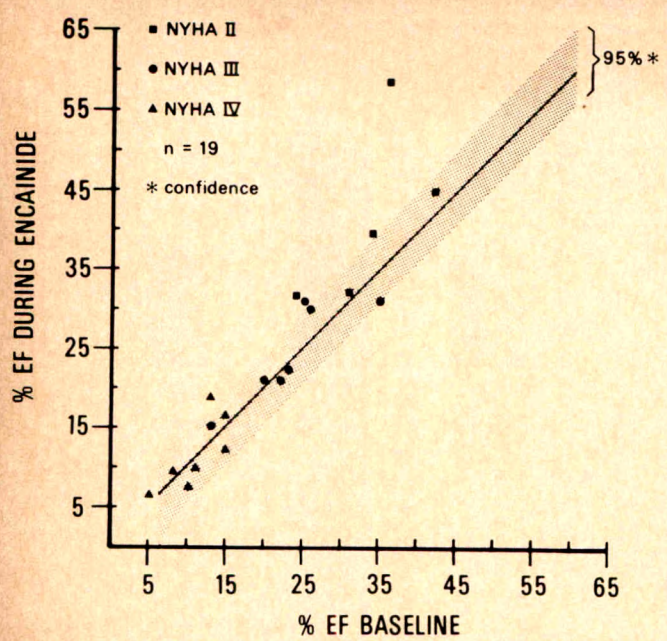

FIGURE 3. Ejection fractions (EF) before and during encainide. Using as background the graph described in Figure 1, we plotted on the abscissa baseline values for EF measured from gated equilibrium blood pool scanning of the 19 patients of Group II who received encainide. Data obtained during encainide therapy were plotted on the ordinates. Patients in New York Heart Association (NYHA) class II are represented by **squares,** those in class III by **circles** and those in class IV by **triangles.**

Discussion

EFs measured by gated cardiac blood pool scans correlate well with those obtained at cardiac catheterization.[17] However, to serially evaluate the effect of 1 drug on any index of cardiac function, the reproducibility of the test must first be defined. Our data suggest that the reproducibility of EF as measured by gated scans in our institution is excellent (Fig. 1). Using the technique we had previously used to test reproducibility of frequency of premature ventricular complexes on Holter monitor recording,[16] we demonstrated that there was no significant change in EF after 1 to 2 weeks of steady-state oral dosage of encainide in patients with depressed LV function; nor did we observed any worsening of clinical congestive heart failure over this period. This is especially significant because the majority of our patients had congestive heart failure of New York Heart Association class III or IV severity. DiBianco et al[10] reported similar observations in a smaller number of patients with severe ventricular arrhythmias, some of whom also had depressed LV function. Anderson et al[18] also found that encainide was well tolerated; they did not note adverse hemodynamic effects in 22 patients with refractory ventricular arrhythmias.

In the presence of arrhythmias, variation of the RR interval may result in a less-than-optimal reconstruction of an idealized average cycle. Error may be somewhat minimized, however, by rigid arrhythmia filtering to look at a more uniform pattern of cardiac contractions. In 1 patient who showed markedly improved EF after encainide therapy, the apparent increase in EF may have reflected, in part, the enhanced accuracy of the gating technique in the presence of a more uniform heart rate rather than a true improvement in LV function.

The lack of significant changes in heart rate and blood pressure during encainide therapy has been demonstrated elsewhere.[10,16] We did not report here the significant electrocardiographic changes in our patients because they have been well described.[8–10,16,18]

Digoxin blood levels showed a minimal, but not statistically significant, increase during encainide therapy. Furthermore, none of our patients developed symptoms or signs of digitalis toxicity. Encainide therapy may therefore present an additional advantage in patients with ventricular arrhythmia who are also taking digoxin, because other antiarrhythmics may significantly increase digoxin plasma concentration and, in some cases, lead to digitalis toxicity.[19]

Encainide and its 2 metabolites, ODE and 3 methoxy ODE, showed marked interpatient variation and a poor correlation with oral dosage in our study. This could be a result of variable liver metabolism of the drug. Roden et al[8] also noted intersubject variation in pattern of metabolism of encainide—1 of 11 patients in their series did not form ODE. An important reason for the apparent lack of correlation between encainide or any of the known metabolites with dosage or clinical response is that 1 or more of encainide metabolites contribute to antiarrhythmic activity.[8] Anderson et al[18] made similar observations in their patients who received steady-state oral doses of encainide. The mean plasma concentration of encainide and its 2 major metabolites in their patients after control of ventricular arrhythmias were similar to those in our patients.

Acknowledgment: We thank Professor Robin Shanks of Queen's University in Belfast, Ireland, and Dr. Raymond Woosley of Vanderbilt University in Nashville, Tennessee, for their measurements of encainide plasma concentrations.

We also thank Josée Roy, RN, and Ruth Ripley, RN, for their valuable assistance in the data collection and Drs. David Stubington, Maurice McGregor and Allan Sniderman of the Royal Victoria Hospital for their help in reviewing the manuscript.

Finally, we acknowledge Susan Anderson and Barbara Stewart for typing the manuscript.

Circulatory Autoregulation in Chronic Congestive Heart Failure: Responses to Head-Up Tilt in 41 Patients

SPENCER H. KUBO, MD, and ROBERT J. CODY, MD

To evaluate mechanisms that regulate the response to postural change in patients with chronic congestive heart failure (CHF), the hemodynamic and vasoactive hormonal responses to head-up tilt were examined in 41 patients. Peripheral venous pooling was present in only 18 patients and was inversely correlated with baseline pulmonary wedge pressure. Baseline supine hemodynamic indexes of these 18 patients indicated less severe CHF compared with those of the 23 patients who did not demonstrate venous pooling. The 18 patients with intact afferent pooling also had lower levels of plasma renin activity and demonstrated increases in both plasma renin activity and norepinephrine on tilt; these reflex increases in vasoactive hormones were not seen in the 23 patients with severe CHF. Overall, 3 patterns could be identified. Of the 18 patients with venous pooling, 12 maintained many of the elements of normal postural response, with increases in systemic vascular resistance and circulating norepinephrine that maintain blood pressure constant. Six patients did not increase resistance in response to peripheral venous pooling and had major decreases in blood pressure analogous to idiopathic orthostatic hypotension. The larger group of 23 patients with more severe CHF did not have peripheral venous pooling and, hence, no afferent stimulus for reflex changes. Thus, the hemodynamic and neurohormonal responses to head-up tilt in CHF are heterogeneous and may be influenced by the severity of disease. The abnormalities of response may reflect the progression of vascular adaptation with loss of myocardial pump function and are important in terms of the pathophysiology and treatment of chronic heart failure.

(Am J Cardiol 1983;52:512–518)

There is an extensive literature describing the hemodynamic response to vasodilator therapy of chronic congestive heart failure (CHF).[1,2] However, few data are available regarding the hemodynamic response to assuming the upright posture, a response first identified as abnormal in CHF by Abelmann and Fareeduddin.[3] Head-up tilt normally results in significant pooling of blood in the venous capacitance vessels, resulting in decreased filling pressures and cardiac output (Fig. 1). This stimulates a reflex increase in heart rate and systemic vascular resistance[4–6] and activation of the renin-angiotensin-system[7,8] and sympathetic nervous system[9,10] to prevent orthostatic hypotension. The uniformity of this response and its regulating mechanisms in patients with CHF have not been fully identified. In the present study, we examined the hemodynamic and vasoactive hormonal responses to head-up tilt in 41 patients with severe chronic CHF to determine the characteristics of the reflex changes that protect circulatory integrity. To place the CHF response to tilt in appropriate context, this was also compared to the response of idiopathic orthostatic hypotension, where baroreceptor regulation is totally deficient.

Methods

Forty-one patients with severe chronic CHF (New York Heart Association functional class III or IV) were studied. Thirty-four were men and 7 were women, aged 20 to 77 years. Sixteen patients had an idiopathic dilated cardiomyopathy and 25 patients had a cardiomyopathy secondary to coronary artery disease. All patients were hospitalized in a metabolic ward and maintained on a 100-mEq/day sodium diet. Previous vasodilator therapy was discontinued for at least 4 days before this study. Most patients were maintained on digoxin and diuretic therapy without alteration of dosage. All other cardioactive drugs were discontinued.

Hemodynamic studies were performed after an overnight fast, withholding the morning dose of diuretic. Heart rate was monitored from a precordial lead. Arterial blood pressure was continuously recorded by placing a cannula in a radial artery and was expressed as the electronically damped mean. Right atrial pressure, pulmonary artery pressure, pulmonary capillary wedge pressure and cardiac output were measured with a thermodilution catheter. Cardiac output was determined

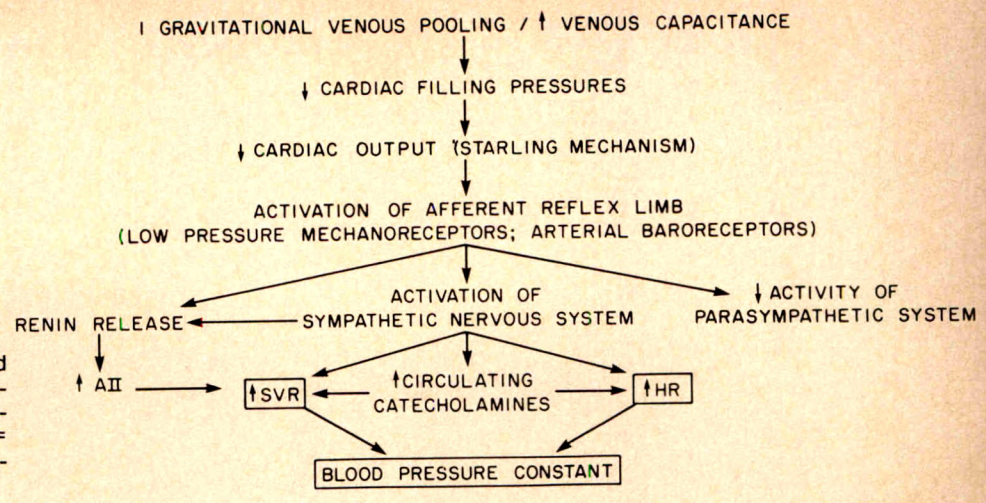

FIGURE 1. The normal hemodynamic and neurohormonal responses to the gravitational stress of upright posture and venous pooling. AII = angiotensin II; HR = heart rate; SVR = systemic vascular resistance.

in triplicate and corrected for body surface area. Systemic vascular resistance was calculated as (mean arterial pressure − mean right atrial pressure/cardiac output) × 80. Pressure recordings were obtained by electronic damping and simultaneously recorded on a strip-chart recorder. After catheter placement, the patients remained in the supine position for 1 hour. Baseline measurements were recorded twice, 30 minutes apart. Upright hemodynamics were determined by tilting the patient on an electric table to 60° for 10 minutes, a level that provides maximal hemodynamic response to venous peripheral pooling.[5] Pressure transducers were attached to a swivel on the table so that they remained at the same level of the atria and maintained the phlebostatic level described by Rushmer[6] during tilt.

For comparison to the CHF group, the hemodynamic response to tilt for normal subjects and patients with idiopathic orthostatic hypotension was summarized from previous data.[11,12]

Plasma renin activity was estimated by radioimmunoassay of angiotensin I generated in vivo.[13] In normal subjects, the range for plasma renin activity is based on a nomogram relating to the 24-hour urinary excretion of sodium; this relationship is not preserved in patients with CHF, but for normal persons with a moderate sodium intake, the upper limit of normal is 6 ng/ml/h. Plasma norepinephrine and epinephrine levels were determined by radioenzymatic assay.[14] Normal values are 165 ± 66 and 23 ± 19 pg/ml, respectively.

Correlations were obtained by linear regression analysis. A Student t test was used for comparison of mean supine values and a paired t test was used to evaluate the changes between supine and tilt values, as each patient served as his own control. Values represent the mean ± 1 standard error of the mean.

Results

Hemodynamic response to head-up tilt: The hemodynamic response to tilt in 7 normal subjects is diagrammed in Figure 2. Tilt caused marked peripheral venous pooling, as reflected by a 22% reduction of cardiac index. Because of reflex increases in heart rate (22%) and systemic vascular resistance (33%), there was no change in arterial pressure. In 8 patients with idiopathic orthostatic hypotension, tilt caused a more marked fall in cardiac index (−37%). Due to the blunted responses, the increases of heart rate (5%) and systemic vascular resistance (9%) were insufficient to prevent a

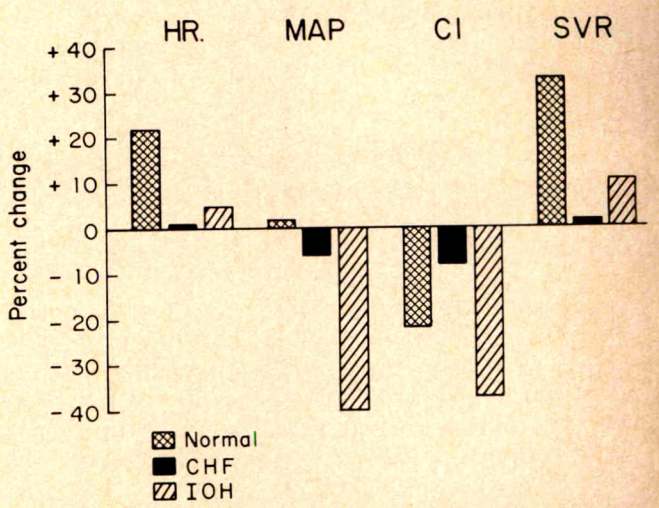

FIGURE 2. The overall qualitative responses to head-up tilt in 3 groups of patients: normal subjects, patients with congestive heart failure (CHF), and patients with idiopathic orthostatic hypotension (IOH). In normal subjects, mean arterial pressure (MAP) is maintained in the presence of the gravitational decrease of cardiac index (CI), due to the reflex increase of heart rate (HR) and systemic vascular resistance (SVR). In chronic CHF, the afferent stimulus of the reduction of CI is not present in the overall group of patients, so that HR and SVR do not change. In patients with IOH, there is an inadequate increase of HR and SVR to the gravitational stress of the CI reduction. Therefore, a marked reduction of MAP occurs.

marked orthostatic reduction of blood pressure (−40%). The response of CHF patients was unlike that of the normal or idiopathic orthostatic hypotension groups. Overall, tilt caused only an 8% reduction in cardiac index, with only small increases in heart rate (2%) and systemic vascular resistance (2%) and a small decrease in blood pressure (−6%). To determine the uniformity of the response to postural change in terms of the ability to stimulate reflex regulatory mechanisms, we evaluated individual tilt responses in the CHF group.

Afferent peripheral venous pooling in congestive heart failure: The extent of the decrease in cardiac index (i.e., peripheral venous pooling) was evaluated as a function of supine cardiac filling pressures. The de-

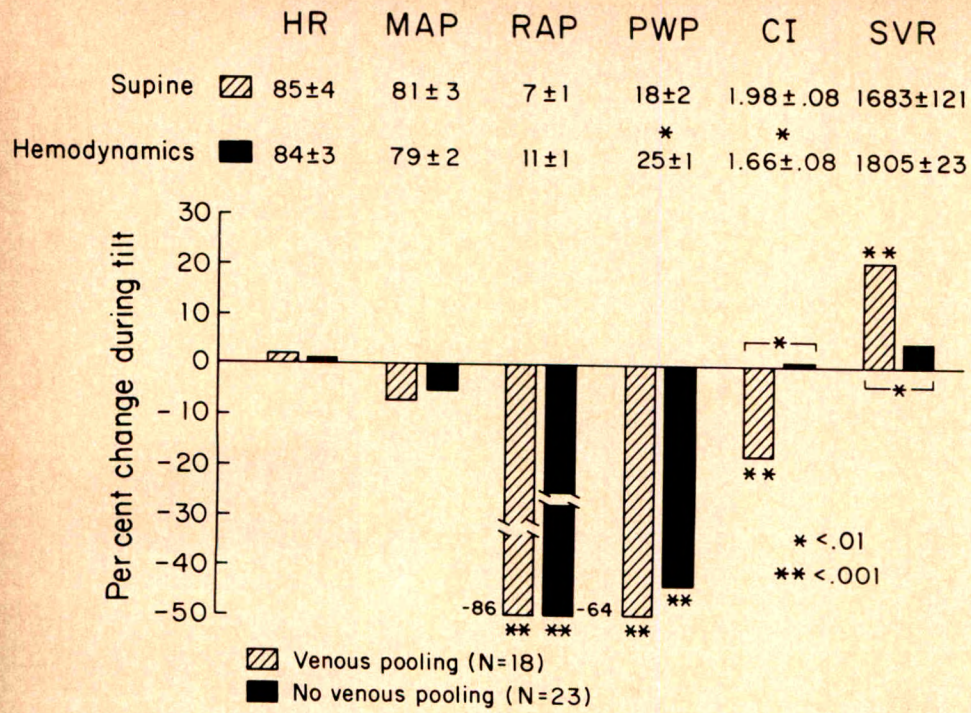

FIGURE 3. Upper portion, the supine hemodynamics for patients with congestive heart failure (CHF) with venous pooling compared with CHF patients without venous pooling. There was a statistically significant difference of supine pulmonary wedge pressure (PWP) and cardiac index (CI) for the 2 groups, and the differences of right atrial pressures (RAP) were small but statistically significant ($p < 0.05$). Although there was a difference in supine systemic vascular resistance (SVR) (1683 versus 1805), this did not achieve statistical significance. **Lower portion,** during head-up tilt, there were comparable reductions of RAP and PWP compared with respective supine values. By definition, the magnitude of reduction of CI during tilt was different for the 2 groups. For the group with venous pooling, mean arterial pressure (MAP) did not change because of the significant (19%) increase of SVR. This reflex increase was sufficient to avert orthostatic hypotension. In the patients with no venous pooling, there was no afferent stimulus for increase of SVR. There was no significant change of heart rate (HR) for either subgroup.

crease in cardiac index during tilt was inversely correlated with baseline pulmonary capillary wedge pressure ($r = -0.450$; $p < 0.01$) and was most apparent in patients with a wedge pressure <15 mm Hg. However, there was wide scatter along the regression line, and the presence of pooling during head-up tilt was not uniform, since 23 of 41 patients did not have a substantial fall (>10%) in cardiac index. This suggests that the first major abnormality in baroreceptor regulation was the presence or absence of peripheral venous pooling. Figure 3 shows the hemodynamic responses of the 18 patients who demonstrated afferent peripheral venous pooling and for the 23 patients who did not. In the baseline supine position, there was no significant difference between the two groups in heart rate, mean arterial pressure or systemic vascular resistance. However, the differences in baseline pulmonary capillary wedge pressure and cardiac index were highly significant. The difference in right atrial pressure was also significant ($p < 0.05$). Thus, the supine hemodynamic indexes of the group of patients with relatively intact venous pooling indicated less severe CHF compared with those of the larger group of patients without pooling.

The hemodynamic response to tilt was also different for these two groups (Fig. 3). In response to peripheral venous pooling ($n = 18$), there was a significant increase of systemic vascular resistance sufficient to prevent orthostatic hypotension. Despite similar reductions in cardiac filling pressures, the patients without peripheral pooling ($n = 23$) did not stimulate a compensatory increase in systemic vascular resistance so that only a small reduction of mean arterial pressure occurred. For both groups, there was a notable absence of reflex tachycardia.

Vasoactive hormonal response to tilt: For the total CHF group, there was a wide range of baseline plasma renin activity in the supine position without a significant change during head-up tilt (Fig. 4). When subdivided according to the presence or absence of peripheral pooling, supine plasma renin activity of patients who had venous pooling was significantly lower than that in patients without pooling (4.3 ± 1 versus 16.4 ± 4.3, $p < 0.02$), indicating less activation of the renin-angiotensin system. In addition, the change in plasma renin activity during tilt was different; patients with pooling showed a 40% increase ($p < 0.01$) and patients without pooling showed a minimal (7%) decrease.

Catecholamine levels were measured in 25 patients (Fig. 5). For the total group, there was a wide range of levels of norepinephrine in the baseline supine position, but no increase during head-up tilt. There was no difference in supine values for the pooling versus non-pooling groups. However, the pooling group did have a significant increase (28%) in norepinephrine levels ($p < 0.01$), whereas norepinephrine levels did not increase in the non-pooling group. For epinephrine, there was no difference in supine levels for the 2 groups, nor any significant change during tilt for either group. The changes in norepinephrine and epinephrine levels were not concordant; an increase in 1 catecholamine was not always associated with an increase in the other. Furthermore, the catecholamine response was not correlated with hemodynamic changes during tilt.

Hemodynamic patterns during head-up tilt in chronic heart failure: The hemodynamic response to tilt in patients with relatively normal peripheral venous pooling could be further divided into two subsets (Fig. 6). In 12 patients (Group A), blood pressure remained

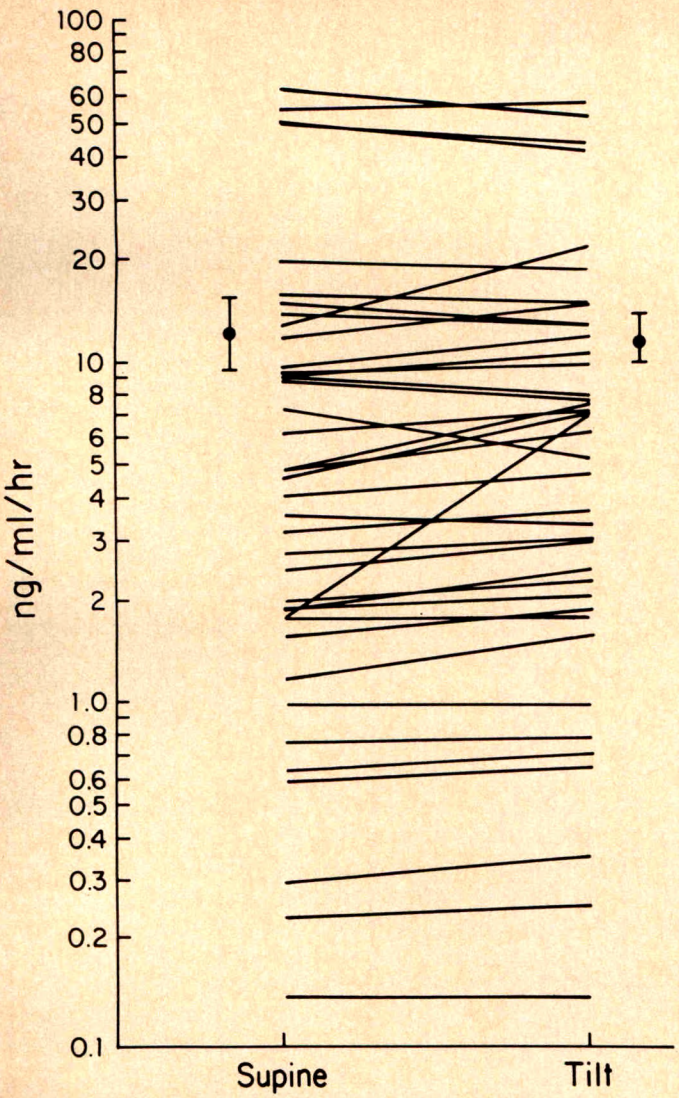

FIGURE 4. Despite a wide range of supine plasma renin activity (0.14 to 66 mg/ml/h), there was no significant increase in plasma renin activity for the 41 patients with congestive heart failure.

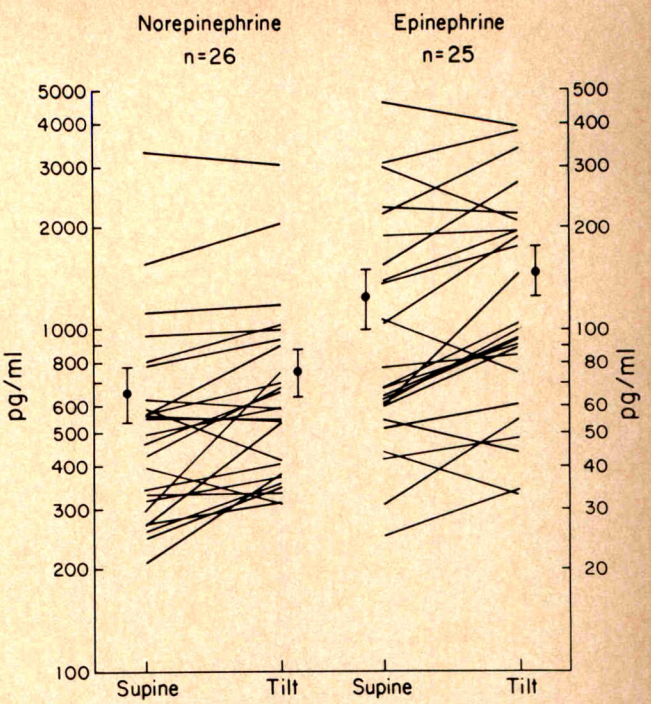

FIGURE 5. Plasma catecholamine levels were available for most of the patients in this study. Overall, there was no trend of response for norepinephrine and epinephrine during head-up tilt.

constant during tilt despite significant reductions of cardiac index, due to a significant reflex increase of systemic vascular resistance. In contrast, in 6 patients with similar reductions of cardiac index and filling pressures (Group B), marked orthostatic hypotension developed during tilt (−30%) because of an inadequate increase of systemic vascular resistance. There were no differences in supine hemodynamic indexes or supine vasoactive hormones between these subsets. The increase of plasma renin activity in the overall group of 18 patients was no longer significant when patients were divided into these subsets. Norepinephrine levels were available for 9 of the 12 Group A patients and showed a significant increase (532 ± 80 to 696 ± 73; $p < 0.02$). Epinephrine levels did not increase significantly in either subset.

Patient characteristics were examined for trends in each subset. There was no differentiation based on the presence of predominantly left ventricular failure versus biventricular failure or on the cause of CHF (ischemic versus nonischemic). All patient groups also had comparable degrees of excess edema.

Thus, the hemodynamic response to tilt in CHF was heterogeneous and could be divided into 3 patterns (Fig. 7). The hemodynamic variables of the 18 patients who had relatively intact peripheral pooling indicated less severe CHF compared to the 23 patients without pooling. Of the 18 patients who had pooling, 12 (Group A) had a reflex increase of systemic vascular resistance that was sufficient to prevent orthostatic hypotension despite the absence of reflex tachycardia or increase of plasma renin activity. Six patients (Group B) did not have reflex increases in resistance in response to venous pooling, and thus demonstrated marked orthostatic reduction of blood pressure. The largest group of patients (Group C, n = 23) which had more severe CHF, did not demonstrate afferent venous pooling, and thus did not have reflex efferent responses.

Discussion

In the normal response to gravitational stress of head-up tilt, the venous capacitance vessels accommodate an even larger proportion of the total blood volume causing both cardiac filling pressures and cardiac output to fall. Since cardiac output is a function of venous return, the reduction of cardiac index during tilt has been used as a measure of peripheral pooling. This venous pooling is difficult to quantify directly and may also depend on the ratio of cardiopulmonary blood volume to total blood volume.[11,15] In previous studies,[11,15] pooling was directly proportional to the reduction of cardiac output and is presumed to be present

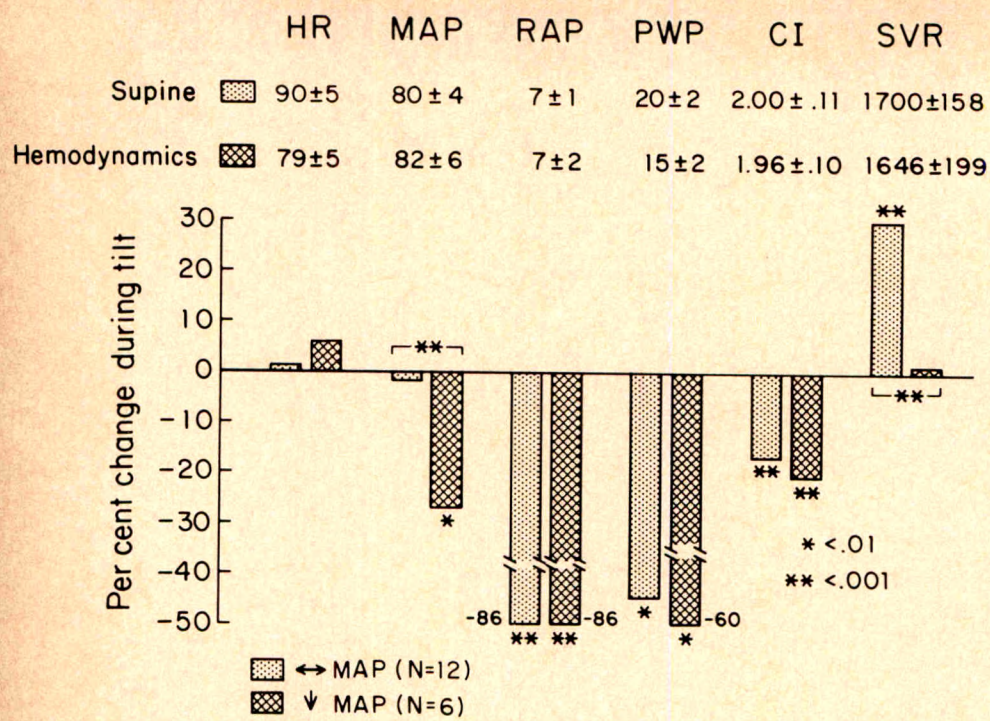

FIGURE 6. The 18 patients who demonstrated orthostatic reduction of cardiac index (CI) during tilt could be subdivided into patients who maintained blood pressure (↔MAP) (n = 12) and those who developed orthostatic hypotension (↓MAP) (n = 6)) during tilt. There was no significant difference of supine hemodynamics between the groups. Furthermore, during tilt, the magnitude of reduction of cardiac filling pressures and CI were comparable. However, the group of patients without orthostatic hypotension reflexly increase systemic vascular resistance (SVR), whereas those who developed orthostatic hypotension had an inadequate reflex increase of SVR, so that MAP fell. In neither group was there reflex tachycardia during tilt. HR = heart rate; RAP = right atrial pressure; PWP = pulmonary wedge pressure.

whenever cardiac output falls during tilt. When peripheral venous pooling and reduction of cardiac output activate atrial and low pressure mechanoreceptors, the neurohormonal efferent limb consists of decreased parasympathetic discharge, increased sympathetic discharge with an increase of circulating norepinephrine, and activation of the renin-angiotensin system.[7–10,16,17] The compensatory hemodynamic response is manifest by tachycardia and an increase in systemic resistance, which maintain blood pressure despite the 20 to 30% reduction of cardiac index.

In the present study of 41 CHF patients, the first major abnormality was the absence of tilt-induced peripheral pooling in 56% of the patients. Based on supine hemodyamics, the majority of patients (56%) with relatively intact pooling had lesser degrees of CHF. The extent of pooling was inversely correlated with supine pulmonary capillary wedge pressure, suggesting a continuum of autonomic dysfunction and hemodynamic reactivity in CHF. This continuum may be more apparent when the progression of CHF in a single patient is studied during extended follow-up.

The absence of afferent peripheral venous pooling in Group C patients is difficult to explain. It has been suggested that the ability to increase venous capacitance in the extremities of patients with chronic CHF is markedly reduced.[18,19] This reduction in capacitance is most likely secondary to generalized reflex venoconstriction, which may occur as a compensatory mechanism to increase cardiac output in the early stages of myocardial pump failure.[18] Other important factors include increased blood volume,[3] increased levels of circulating catecholamines,[4] and local extrinsic factors such as tissue edema, which decreases venous distensibility.[20] This last factor was recently identified as preventing venous pooling in patients with marked edema secondary to cirrhosis and the nephrotic syndrome.[21] Thus, in severe CHF, one might anticipate that the increase of venous capacitance during the stress of postural change would be markedly attenuated, and the afferent stimulus for activation of hemodynamic and neurohormonal pathways does not occur. This relatively fixed circulatory tone can be modified by vasoactive drugs, as demonstrated by the first dose administration of captopril.[4]

Group A patients (Fig. 7) had an increase in systemic resistance sufficient to maintain blood pressure. The magnitude of this increase was inversely correlated with the magnitude of cardiac output reduction. The increase in resistance was not accompanied by an increase of renin or circulating epinephrine. However, plasma norepinephrine levels, measured in 9 of these patients, did increase significantly, indicating some preservation of sympathetic responsiveness. Although these patients had better supine hemodynamic values than Group C, multiple clinical variables did not further characterize this group. Thus, some patients with less severe CHF respond to the afferent stimulus of pooling with many of the elements of the normal efferent response.

The 6 patients in Group B (Fig. 7) had marked abnormalities of the efferent response to head-up tilt, and experienced marked orthostasis. This response is analogous to patients with idiopathic orthostatic hypotension, although by standard clinical criteria, these patients did not have this problem or other common causes of orthostatic hypotension. This particular subset may not tolerate vasodilator therapy and may require alternate therapy with inotropic agents. Orthostatic hypotension in this group was not related to differences in baseline filling pressures.

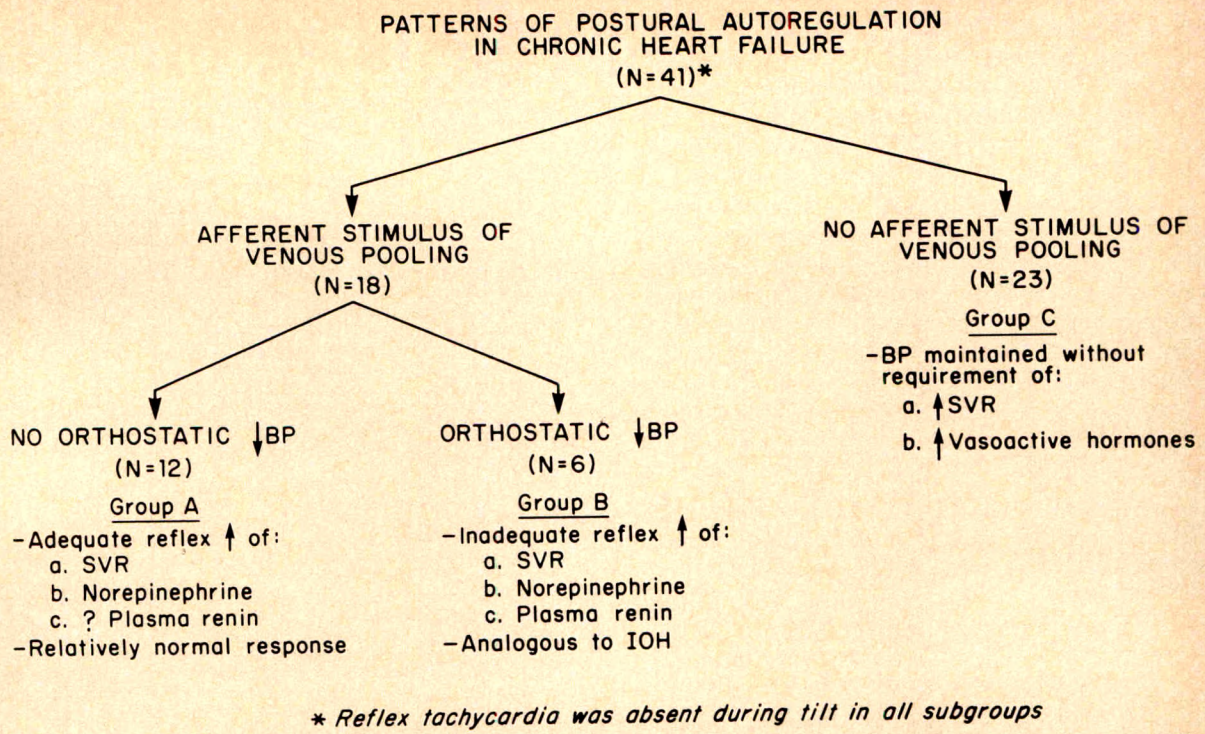

FIGURE 7. The hemodynamic and neurohormonal response of circulatory autoregulation in heart failure were divided into 3 groups. Patients who had the afferent stimulus of venous pooling were subdivided into those who had no orthostatic reduction of blood pressure (no orthostatic ↓BP) (Group A) owing to relatively normal autoregulation, and those who had significant orthostatic reduction of BP (Group B) owing to an inadequate hemodynamic and neurohormonal response to peripheral pooling. Group B patients are analogous to patients with idiopathic orthostatic hypotension (IOH). Group C patients had no afferent stimulus of venous pooling during head-up tilt. Therefore, there was no efferent response of hemodynamic and neurohormonal pathways. SVR = systemic vascular resistance.

The potential effect of diuretics on the different patterns of response must also be considered. All patients were receiving furosemide and, in many cases, a thiazide-like preparation. Unlike other disease entities,[21] diuretic therapy of patients with CHF may change supine hemodynamics but not the qualitative response to tilt,[22] because blood volume usually remains expanded. In a recent study,[23] there was no significant qualitative change in the tilt response of individual CHF patients, who were studied in balance during both sodium depletion (10 mEq) and sodium repletion (100 mEq). These patients also did not have a significant change in total blood volume as dietary sodium was altered. Thus, it is unlikely that variation in diuretic dosage has a major influence in differentiating these 3 patterns of hemodynamic response to tilt.

Heart rate remained relatively constant in all 3 patterns despite the wide range of hemodynamic changes during tilt. Abnormalities of heart rate responses due to changes in parasympathetic and sympathetic tone have been identified.[3,4,24,25] The present data further emphasize that the heart rate response to physiologic maneuvers and vasodilator therapy must be interpreted in light of underlying autonomic dysfunction.

The renin-angiotensin system is activated to a variable degree in CHF, as manifest by the wide range of baseline supine plasma renin activity.[26] Patients with relatively intact pooling had lower supine plasma renin activity overall, and retained some degree of renin responsiveness to tilt. For Group C patients, the lack of a tilt-induced increase of renin may represent blunted efferent responsiveness or inadequate stimulus of cardiopulmonary mechanoreceptors. In contrast to the latter abnormality, plasma renin activity can be changed by dietary sodium manipulation in CHF.[23] This suggests a dissociation of cardiopulmonary reflex and macula densa signals for renin release. In a recent study, with classification of patients by stress hormone levels, subgroups of renin responses during ambulation were identified.[27] However, ambulation, through muscular contraction in the lower limbs, results in venous compression with reversal of pooling,[28] so this renin response may be more analogous to exercise.

Despite similarities of supine norepinephrine levels in Groups A and C, only Group A retained the ability to reflexly increase norepinephrine. This preserved sympathetic responsiveness may be another useful guide to monitor the progression of CHF. Although sympathetic responsiveness is usually attenuated with severe CHF, this may be reversible. After hemodynamic improvement with long-term captopril therapy, norepinephrine responsiveness to tilt has been demonstrated.[29] Levine et al[30] demonstrated normalization of the norepinephrine response to tilt and exercise after successful heart transplantation.

The importance of understanding the response to head-up tilt in patients with heart failure is emphasized by several factors. First, the heterogeneity of the ab-

normalities seen in the present study may help to explain some of the discrepancies between supine and upright exercise.[31] Second, supine filling pressures appear to be important determinants of peripheral pooling, but there is no "critical" filling pressure for orthostasis in CHF. Third, physiologic maneuvers such as head-up tilt are necessary to clarify pathophysiologic mechanisms in CHF, given the paucity of applicable animal model data. Fourth, understanding the heterogeneity of response may aid in the choice of appropriate drug therapy and minimize side effects such as orthostatic hypotension. Finally, a better understanding of circulatory autoregulation may be necessary for the analysis of CHF in its progression from mild to more severe symptoms.

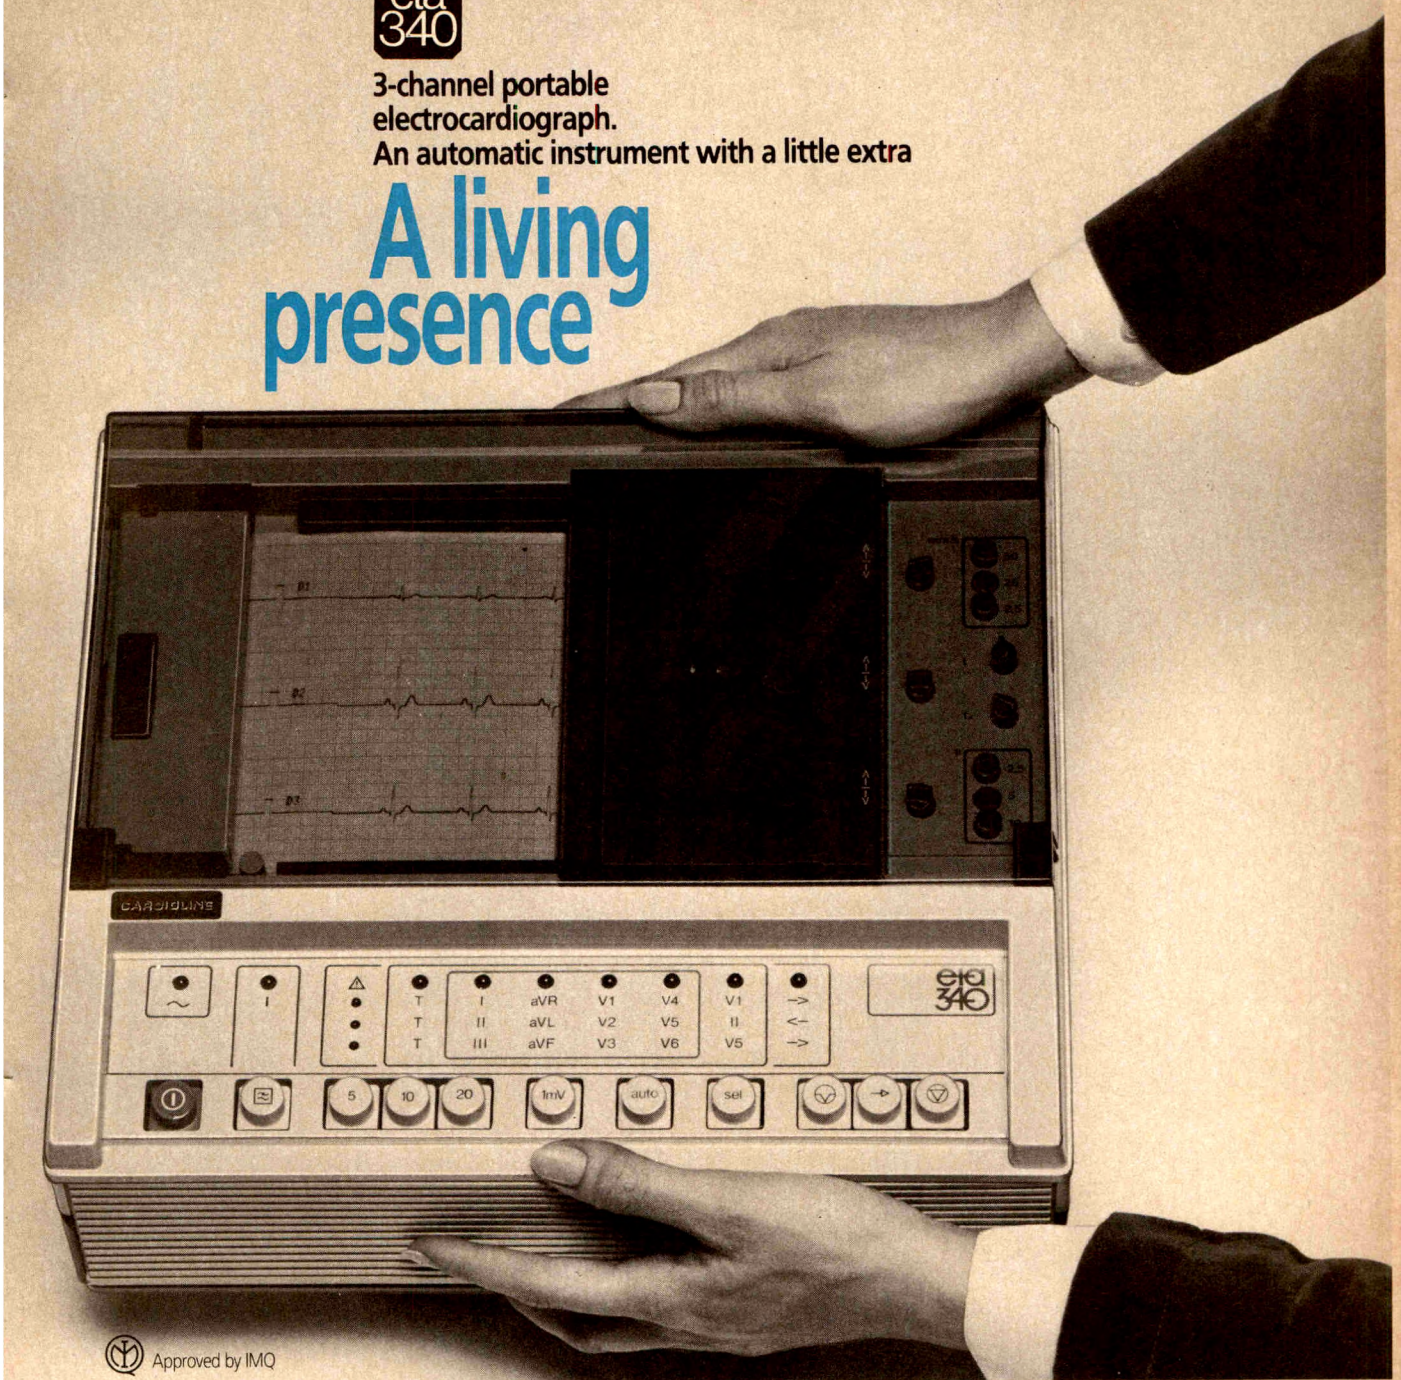
CARDIOLINE®

eta 340

3-channel portable electrocardiograph.
An automatic instrument with a little extra

A living presence



Approved by IMQ

Automatic	Performs the ECG leads in automatic mode and has each group of three leads preceded by alphanumeric identification and calibration.
Functional	Centres ECG signals automatically.
Autonomous	Signals detachment of an electrode or the presence of defibrillation potentials. Reverts to incorporated power pack or accumulator battery immediately in the event of a power cut.
Flexible	It has available an ergometry program and a program for combination with two auxiliary inputs (phono-pulse or others), plus an output for the monitor. The operator may also override automatic mode operation.

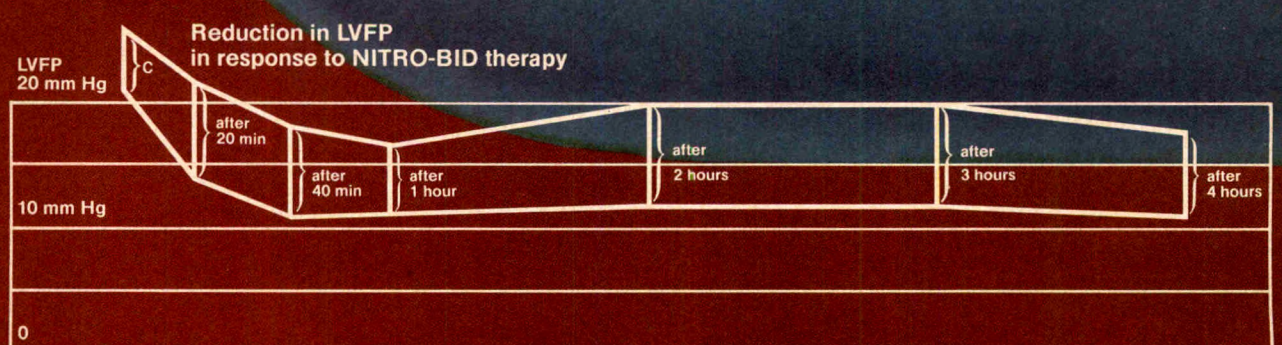
DYNAMIC



plus a dosage range for most angina* patients in your practice

"...objective evidence of the... hemodynamic effects of ONTG [oral nitroglycerin].... [shows] LVFP [left ventricular filling pressure] was significantly reduced from 23 mm Hg to 17 mm Hg ($p<0.01$) 20 min after administration of ONTG and this effect persisted over the entire four hours...."†[1]

"After the administration of sustained-release nitroglycerine, peak effects were seen in about 2 hours. However significant effects were still seen at 4 and 6 hours in most patients."[2]

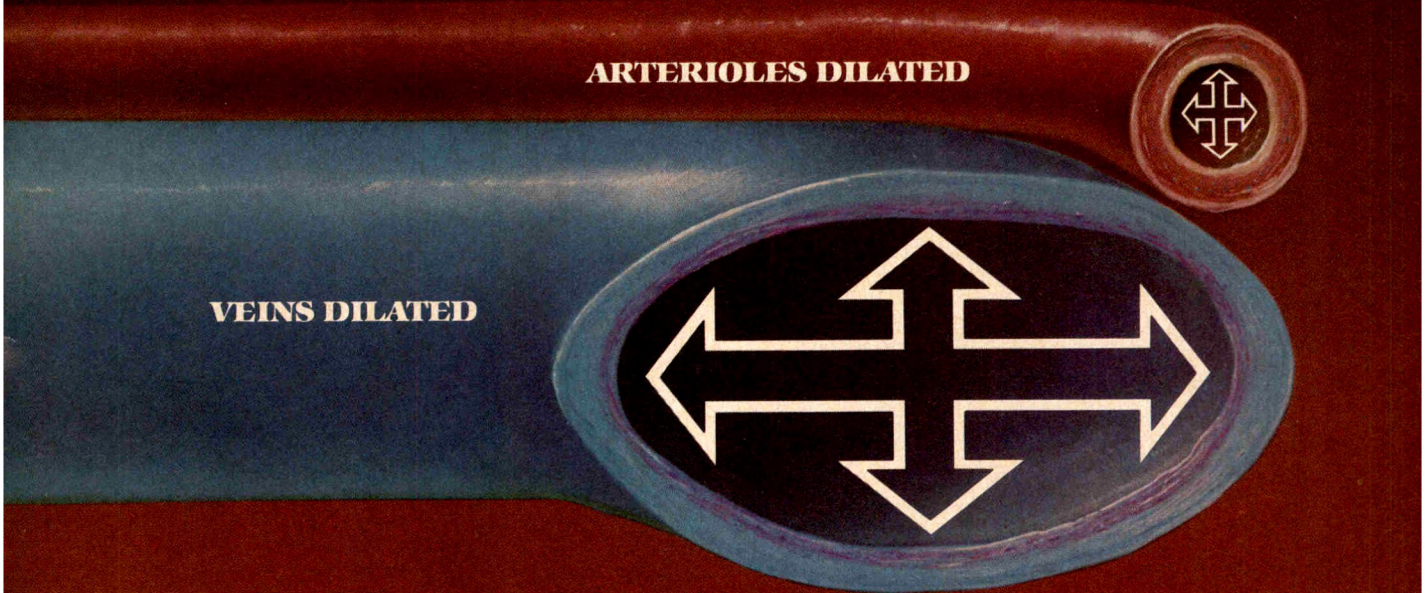
Nitro-Bid Capsules are available in three dosage strengths to meet the needs of most angina patients and to help return each patient to a more normal life.

NITRO-BID® Capsules
(nitroglycerin)
9mg, 6.5mg, 2.5mg

* This product has been evaluated as possibly effective for this indication. See Professional Use Information.

†Although the reduction in hemodynamic effects continued for more than four hours, the study was discontinued after that period of time.

HEMODYNAMIC RESPONSE



NITRO-BID® Capsules (nitroglycerin) 9mg, 6.5mg, 2.5mg

Professional Use Information

NITRO-BID® CAPSULES (nitroglycerin)

* **INDICATIONS:** Based on a review of this drug and a related drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS: Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure, and idiosyncrasy to the drug.

WARNINGS: Capsules must be swallowed, FOR ORAL, NOT SUBLINGUAL, USE. NITRO-BID® 2.5, NITRO-BID® 6.5, and NITRO-BID® 9 Controlled-Release Capsules are not intended for immediate relief of anginal attacks.

PRECAUTIONS: Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth, or lack of benefit occurs, the drug should be discontinued.

ADVERSE REACTIONS: Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

Cordis Corporation, P.O. Box 025700, Miami, Florida 33102-5700, U.S.A.

Important Information
Cordis Implantable Pacers and Programmers

Indications and Contraindications
The medical literature describes currently accepted indications and contraindications for the various pacing/sensing modes. However, the physician's clinical experience and judgment must ultimately determine the pacing mode best suited to the patient's needs.

When spontaneous beats are expected, a sensing mode (inhibited or triggered) is indicated. *Asynchronous pacing is contraindicated for long-term pacing when inherent activity is present or likely to be present in the chamber being paced.*

Pacing of the ventricles (VVI or VVT) is indicated for controlling slow heart rate in patients with A-V block and/or sick sinus syndrome. Atrial pacing (AAI or AAT) is indicated for controlling heart rate, increasing cardiac output, and suppressing premature ventricular contractions (PVCs) in patients with intact A-V conduction and sick sinus syndrome. *Atrial pacing is contraindicated when A-V conduction disturbances are present.*

Atrial-synchronized ventricular pacing (VDD or VAT) and dual-chamber pacing (DVI or DDD) are indicated for patients who would benefit from restoration of atrial contribution to cardiac output and the control of heart rate. Atrial-synchronized ventricular pacing is indicated for patients with permanent heart block and normal atrial rhythm. Dual-chamber pacing is indicated for A-V conduction disturbances with sinus node dysfunction (sinus bradycardia with A-V block, bradytachy syndrome). *Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated in the presence of persistent atrial flutter or atrial fibrillation.* The VVI mode is recommended for these conditions.

Cordis programmers are designed to noninvasively control the operating parameters and modes of Cordis programmable cardiac pacers.

Precautions
Cordis implantable pacers may respond to programmers of other manufacturers. Because of the unknown nature of such response, use only the Cordis Model 255A Programmer III for reprogramming.

Use pacers on a first-in, first-out basis prior to the "Use before" date on the package.

Warnings
None

Adverse Effects
A number of complications related to pacer therapy have been reported in the medical literature. The complications listed below may occur at any time after implantation.

Pacer – battery depletion, electromagnetic interference, component malfunction, decreased sensitivity.

Lead – unsatisfactory electrode position, fracture, displacement, perforation of heart wall, faulty connection with pacer, migration through body tissue.

Patient – reaction, infection/erosion, increase in stimulation threshold, embolism, thrombosis.

Caution: Federal (U.S.A.) law restricts these devices to sale by or on the order of a physician.

Prior to use, refer to the *Instructions for Use* for more information.

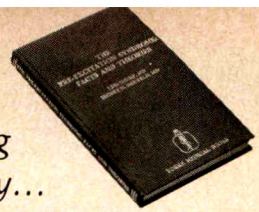
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

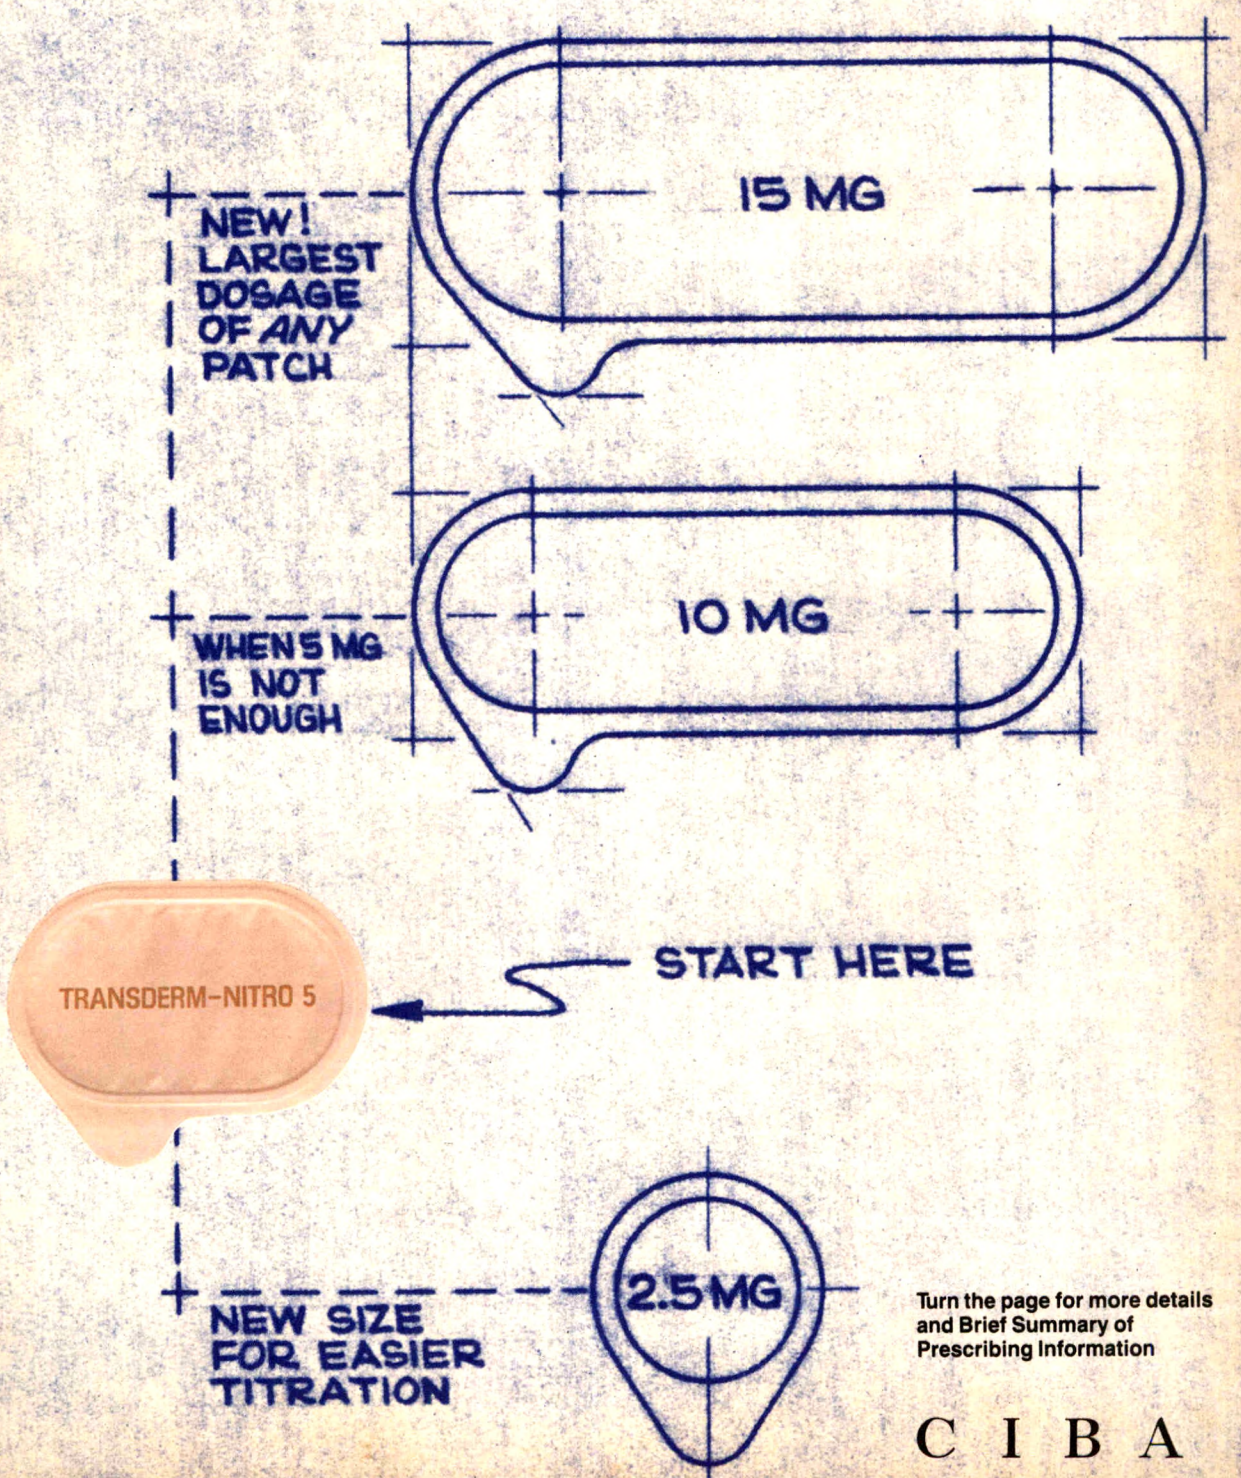
Now...custom-built anginal therapy

Transderm®-Nitro

nitroglycerin

More sizes...more flexibility...
more precise titration



Turn the page for more details and Brief Summary of Prescribing Information

CIBA

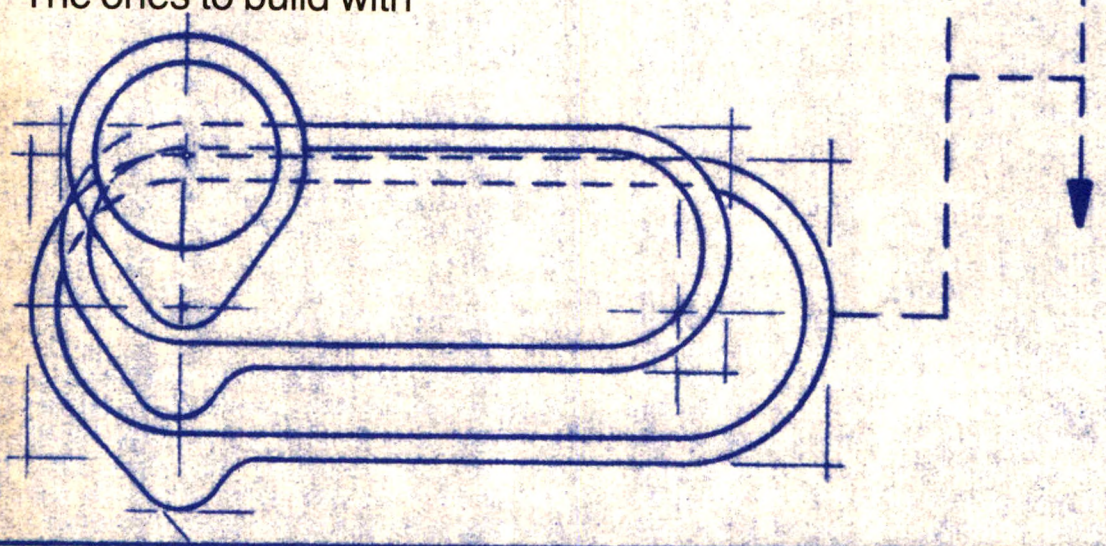
Transderm®-Nitro
nitroglycerin

New dosage versatility—more useful than ever

The complete line: 2.5 mg, 5 mg, 10 mg, 15 mg

The one to build on

The ones to build with



- consistent 24-hour anginal control with one, simple 10-second application
- small, convenient, easy to use
- dosage strength is clearly marked on the front for easy identification

Side effects include transient headaches and orthostatic hypotension. Contraindicated in patients with increased intraocular pressure. Withdrawal from treatment should be gradual.

Consult complete product information before prescribing.

C I B A

First with the future in drug delivery systems

Transderm®-Nitro (nitroglycerin) **Transdermal Therapeutic System**

Brief Summary of Prescribing Information.

INDICATIONS AND USAGE

Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS

Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS

In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS

Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS

Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

Contrast 2-dimensional (2-D) echocardiography was performed during cardiac catheterization to compare the technique with cineangiography in evaluating the presence and severity of aortic (AR) and mitral regurgitation (MR). A physiologic solution was injected through the intracardiac catheter while echocardiograms were recorded in multiple views.

AR was evaluated in 35 patients; an adequate 2-D echocardiogram was obtained in every patient. Cineangiography was adequate for diagnosis in every patient, but in 3 patients AR could not be graded because of technical problems. Twenty-six patients had AR by 2-D echocardiography and cineangiography and 9 did not have AR by either 2-D echocardiography or cineangiography. Thus, the specificity, sensitivity and predictive accuracy was 100% for detection of AR by 2-D echocardiography. Severity of AR was graded (0 to 4+) by visual inspection in both methods, and severity by both methods correlated with r = 0.998.

MR was evaluated in 59 patients. Because of technical problems, MR could not be evaluated by cineangiography in 15, by 2-D echocardiography in 5, or by either method in 2. In 2 patients, although it could be detected, the severity of MR could not be graded by cineangiography. Of 37 patients with satisfactory studies, MR was detected by 2-D echocardiography and by cineangiography in 16; MR was detected only by 2-D echocardiography in 2, only by cineangiography in 3 and by neither method in 16. The sensitivity of 2-D echocardiography for detection of MR was 84%, specificity 89%, positive predictive accuracy 89%, and negative predictive accuracy 84% compared with cineangiography. The severity of MR by both methods correlated with r = 0.998.

Contrast 2-D echocardiography for the evaluation of the presence and severity of AR and MR is both sensitive and specific, particularly for AR. In the cardiac catheterization laboratory, this method should be of greatest value when use of cineangiography is limited by the dose of contrast medium, radiation or by technical problems, particularly those encountered with left ventricular angiography.

(Am J Cardiol 1983;52:519–524)

Contrast echocardiography is a technique that consists of injecting a previously agitated solution through a peripheral vein or intracardiac catheter while echocardiographic recordings are obtained. The contrast effect is a result of microbubbles produced in the solution by the previous agitation and which, although not grossly visible, are detectable by ultrasound.[1] A variety of solutions can cause the contrast effect; the most frequently used are saline solution or dextrose in water, indocyanine green dye, or the patient's blood.[2,3] The method has been used to assess flow patterns in congenital heart disease, to detect intracardiac shunts, and to evaluate the presence of tricuspid insufficiency.[4–6] Contrast M-mode echocardiography has been used during cardiac catheterization to detect aortic (AR) and mitral regurgitation (MR).[7] The severity of the regurgitant lesions, however, cannot be adequately assessed by M-mode echocardiography because of the limited

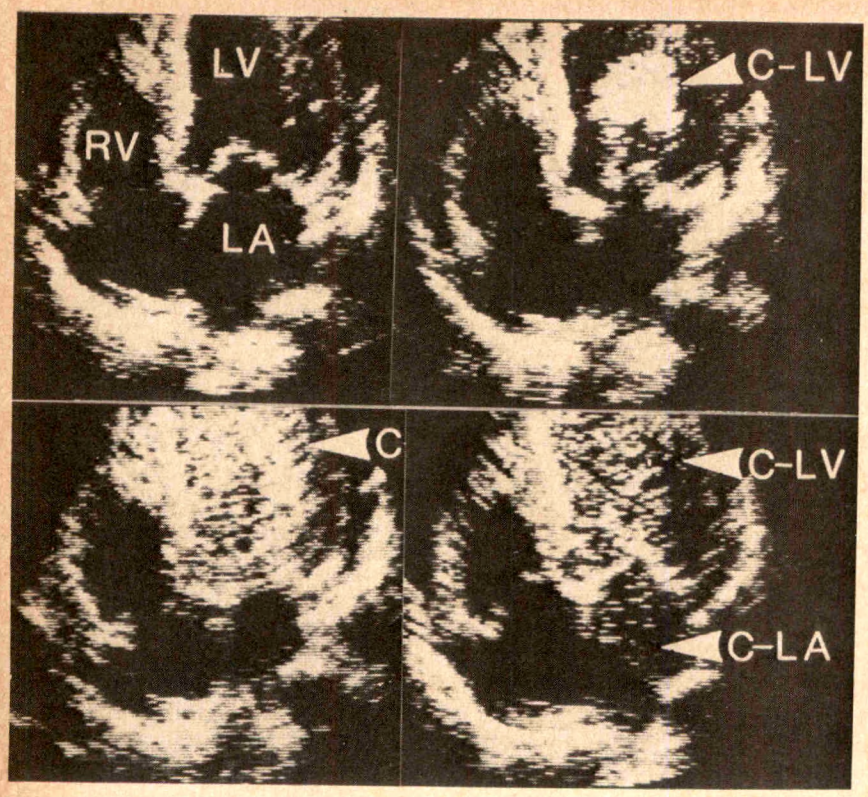

FIGURE 1. Top left, before contrast injection, a 2-dimensional (2-D) echocardiogram in the apical 4-chamber view of a patient with aortic regurgitation. The intracardiac catheter positioned in the aortic root is not visualized in this view. **Top right,** a cloud of microbubbles appears in the left ventricle (LV) immediately after injection of contrast C-LV). **Bottom left,** the microbubbles densely fill the entire left ventricular chamber by the end of the first diastolic interval after the injection. The severity of the aortic regurgitation was graded as 4+ by both 2-D echocardiography and cineangiography. **Bottom right,** a few microbubbles were visualized in the left atrium (C-LA) during systole and was graded as 1+ mitral regurgitation. The mitral regurgitation was graded as 1+ by cineangiography after review by the third angiographer. RV = right ventricle.

view of the intracardiac chambers. Two-dimensional (2-D) echocardiography is particularly useful because of the added spatial orientation that it provides. Therefore, this study compared the accuracy of contrast 2-D echocardiography with a standard semiquantitative cineangiographic method during cardiac catheterization in the assessment of the diagnosis and severity of AR and MR.

Methods

Patients: Sixty patients who underwent diagnostic cardiac catheterization were studied. All contrast 2-D echocardiographic studies were performed by 2 of the investigators; patient selection was based only on the availability of the personnel and the echocardiographic equipment. No patient was excluded because of precatheterization echocardiographic findings. There were 38 males and 22 females, mean age 49 years (range 16 to 75). Thirty-one of the patients had coronary artery disease, 12 rheumatic valvular disease, 5 AR of uncertain cause, 4 infective endocarditis, 2 mitral valve prolapse syndrome, 1 prosthetic valve dysfunction, 2 chest pain with normal coronary arteries, 1 a left atrial myxoma and 2 thoracic trauma. One patient had undergone a second study after prosthetic valve replacement with a Starr-Edwards valve for rheumatic heart disease. Thirty-three patients had undergone both aortic root and left ventricular angiography.

Cardiac catheterization and angiography: Left- and right-sided cardiac catheterizations were performed using the retrograde femoral technique. After measuring left- and right-sided cardiac pressures and cardiac output, left ventricular contrast angiography was performed in the right and left anterior oblique positions. When clinically indicated, supravalvular cineaortography was performed in the left anterior oblique position. AR was graded semiquantitatively from the supravalvular aortogram according to a previously described method[8]: 1+ (mild), contrast material clears with each beat and never fills the left ventricle; 2+ (moderate), faint opacification with the contrast material of the entire chamber; 3+ (moderately severe), opacification of the left ventricle with an intensity equal to the aorta; and 4+ (severe), complete opacification of the left ventricle with the first beat and with appearance of progressively greater intensity than the aorta. MR was graded semiquantitatively from the left ventriculogram as follows[9]: 1+ (mild), the contrast material clears with each beat and never opacifies the left atrium; 2+ (moderate), the contrast material does not clear with 1 beat and opacifies the left atrium after several beats; 3+ (moderately severe), the left atrium opacifies with contrast material to an intensity equal to that of the left ventricle; and 4+ (severe), the left atrium opacifies within 1 beat and becomes progressively more dense with each beat. Premature beats during the left ventriculogram were excluded in the evaluation of MR. Cineangiograms in which the regurgitant chamber was inadequately visualized for grading purposes were included only for detection of the presence of regurgitation. Each cineangiogram was evaluated independently by 2 experienced angiographers for the presence and severity of the regurgitation. The reviewers were blinded at the time of evaluation to each other and to the identity of the patient. When there was a disagreement, a consensus was reached. If that was not possible, a third experienced observer was used for the final interpretation.

Contrast 2-D echocardiography: Two-dimensional echocardiography was performed using an ATL (Advanced Technology Laboratory, Inc.) real-time mechanical sector scanner with a simultaneous electrocardiogram. The images were recorded on a Sanyo videotape system. These recordings were then transferred to a Diasonics Cardio-Revue Center to facilitate playback analysis using a videodisc. The contrast effect was produced by vigorously shaking a 10-ml syringe that contained a dilute standard cardiac catheterization flush solution consisting of 2.5% dextrose in water with 2 U/ml of

heparin. In a limited trial, we found that this solution produced adequate contrast and was then chosen as the contrast agent primarily because it was convenient. After carefully clearing visible bubbles, the solution was rapidly hand-injected through the intracardiac catheter while echocardiographic recordings were made beginning a few beats before the injection and continuing until the microbubbles disappeared. Voice recordings were made on the videotape to describe the catheter position and note the time of the injection. Recordings were made in the supine or left lateral position. Care was taken to avoid movement of the catheter between the echocardiographic and cineangiographic studies.

Contrast 2-D echocardiographic studies with injection into the aortic root were usually performed before supravalvular aortography when the latter procedure was indicated. The parasternal long-axis view was examined first and adjustments were made to obtain the clearest view of the left ventricle and aortic root. Gain settings were adjusted to reduce the level of background noise. The injection was then repeated in other views, including the apical 4-chamber, apical 2-chamber or subcostal position to confirm the findings. AR was considered to be absent if no microbubbles were visualized in the left ventricle in at least 2 views, and, when adequately visualized, a good contrast effect was seen in the aortic root. A study for AR was considered positive when microbubbles were seen in the left ventricle in any echocardiographic view (Fig. 1).

Injections into the left ventricle for detection of MR were made after hemodynamic recordings were obtained and before injection of angiographic contrast media. In 1 patient with coronary artery disease, the angiographic study was performed first, after which the patient developed chest pain, became dyspneic, and the left ventricular pressure was seen to increase. No MR was seen on the angiogram. The contrast 2-D echocardiographic study was then performed and MR was present. The different findings by the 2 techniques could have been explained by the development of left ventricular dysfunction[10] and acute transient MR after left ventricular angiography. Because of this possibility, all contrast echocardiographic studies were subsequently performed before angiographic studies. Echocardiographic views were done in the positions that gave the clearest image of the left atrium with adjustments made to reduce background noise. MR was considered present if microbubbles were seen in the left atrium in any view (Fig. 1) and negative if no contrast effect was seen in the left atrium in at least 2 views. If a premature ventricular contraction occurred during the left ventricular injection, the injection was repeated. In many patients a slightly "off-axis" view was used to obtain the clearest image of the regurgitant chamber. Multiple injections were often necessary to assure adequate recordings and visualization of microbubbles.

AR was semiquantitatively graded by echocardiography as follows: 1+ (mild), only a few microbubbles appear in the left ventricular outflow tract and never reach a density sufficient to outline the left ventricle; 2+ (moderate), the left ventricle is sparsely outlined with the microbubbles, but clears within a few beats; 3+ (moderately severe), the left ventricle is densely filled and, when the aortic root is also visualized, they are of equal density; and 4+ (severe), the left ventricle is densely filled within the first beat and the microbubbles persist for several beats. The severity of the MR assessed by contrast echocardiography was graded as follows: 1+ (mild), appearance of only a few microbubbles of insufficient quantity to outline the left atrium; 2+ (moderate), the left atrium is outlined with the microbubbles after several beats but less densely than the left ventricle; 3+ (moderately severe), the atrium completely fills with microbubbles to a density equal to the left ventricle; and 4+ (severe), the left atrium is filled with microbubbles to a progressively greater density than the left ventricle with each beat. MR associated with premature ventricular contractions was excluded. Each 2-D echocardiographic study was evaluated independently by 2 experienced echocardiographers who were also blinded to the results of the angiography and the identity of the patient. When there was disagreement as to the presence or severity of the regurgitation, a consensus was taken as the final interpretation.

The patients were all observed in the hospital for 24 hours after cardiac catheterization. No neurologic symptoms or complications were noted.

Data analysis: Cineangiograms with excessive premature ventricular contractions or of inadequate technical quality for detection of valvular regurgitation were seen in 17 patients (28%) and were excluded from analysis. In 7 patients (11%), echocardiograms were of inadequate technical quality for analysis. McNemar's chi-square analyses were performed to evaluate the sensitivity of the 2-D echocardiographic technique. Spearman's rank correlation coefficients were calculated to compare the agreement between the semiquantitative method of the 2 techniques.[11] Spearman's rank correlation was used because the variables in this case are discrete and not continuous and, therefore, the usual Pearson correlation is not appropriate. Because the variables are discrete, their correlations tend to be exaggerated compared with those for continuous data. However, the strength of the correlation is not artifactually affected by the statistical calculation. Sensitivity was defined as true positives/true positives + false negatives. Specificity was defined as true negatives/true negatives + false positives. Predictive value of a positive test was defined as true positives/all positives (true positives + false positives); predictive value of a negative test was defined as true negatives/all negatives (true negatives + false negatives).

Results

Aortic regurgitation: AR was evaluated in 35 patients; technically adequate contrast 2-D echocardiograms were obtained in all. Cineangiography was adequate for diagnosis in all, but in 3 patients severity could not be graded.

Twenty-six of the 35 patients had AR by both contrast 2-D echocardiography and cineangiography. Nine patients had no AR by either contrast 2-D echocardiography or cineangiography, yielding a sensitivity, specificity and predictive value of 100% for detection of AR by contrast 2-D echocardiography (Table I) compared with that for cineangiography. Therefore, for detection of AR, there was perfect agreement between the techniques (chi-square = 0, difference not significant [NS]).*

In 20 patients there was exact agreement between 2-D echocardiography and cineangiography in the visual assessment of the severity of the AR. In 12 patients, although the 2 techniques differed, it was not by >1 grading scale (Fig. 2). The Spearman correlation coefficient measuring the degree of association between both techniques was $r = 0.998$ ($p < 0.0001$).

Mitral regurgitation: MR was evaluated in 59 patients. Technical problems prevented the evaluation of MR by cineangiography in 15, by 2-D echocardiography in 5, and by either method in 2. In 2 patients, the severity of MR could not be assessed by cineangiography.

* To calculate McNemar's chi-square analysis, it was necessary to add 0.5 to each cell.

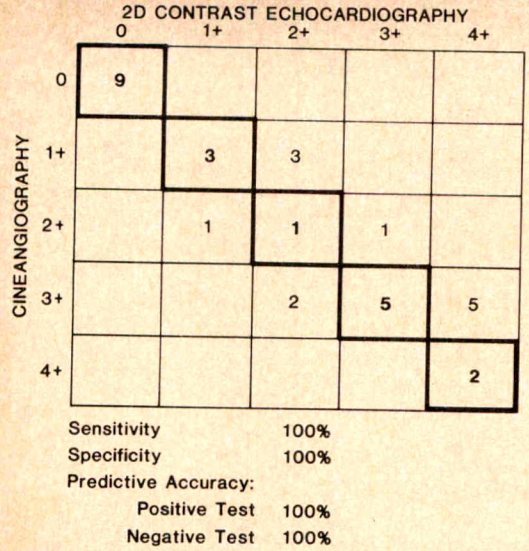

FIGURE 2. The semiquantitative assessment by contrast 2-dimensional (2D) echocardiography and cineangiography of aortic regurgitation.

Of 37 patients with satisfactory studies, results of contrast 2-D echocardiography and cineangiography were both positive in 16. MR was detected only by cineangiography in 3; only by 2-D echocardiography in 2; and by neither technique in 16 patients (chi-square = 0.2, NS). One of the patients with MR detected only by 2-D echocardiography was the patient who had cineangiography first and then developed severe chest pain and possibly acute MR. The other patient was graded 1+ by 2-D echocardiography. The 3 patients who did not appear to have MR by contrast echocardiography all had only 1+ MR by cineangiography. Compared with cineangiography, contrast 2-D echocardiography for detection of MR had a sensitivity of 84%, a specificity of 89%, a predictive value for the presence of MR of 89%, and an 84% predictive value for its absence (Table I).

The association between both techniques for assessment of the severity of the MR measured by Spearman's rank correlation coefficient was r = 0.998 ($p < 0.0001$). Twenty-five of the patients had equal severity of MR assessed by both 2-D echocardiography and cineangiography; in 8 patients there was a difference of 1 grade between both techniques, and in 1 patient a difference of 2 grades (Fig. 3).

Discussion

Our results showed that contrast 2-D echocardiography during cardiac catheterization was highly sensitive and specific in the detection of left-sided valvular regurgitation compared with cineangiography. The semiquantitative assessment of the severity of the regurgitation based on a visual grading scale had an excellent correlation with that obtained by cineangiography. The technique was safe provided care was taken to remove visible bubbles before injection; no complications were noted with this method during the study.

Cardiac catheterization with angiography has been the standard method for assessment of the presence and

severity of valvular regurgitation. Although the semiquantitative assessment by cineangiography has limitations and a discrepancy between it and direct measurement of the amount of valvular regurgitation has been shown, it remains a widely used method.[12] However, it has the following disadvantages: (1) the use of contrast media; (2) a limited number of angiographic views can be obtained (because of the maximal dose of contrast dye that can be used in an individual patient); (3) exposure to radiation; and (4) technical problems such as malpositioning of the intracardiac catheter and patient or premature ventricular contractions that may occur during the angiogram. The latter is a problem particularly with left ventriculography and may prevent accurate evaluation of left ventricular function and the detection and quantitation of MR.

Although contrast 2-D echocardiography does not obviate the need for cardiac catheterization, it could be a useful adjunct to this procedure in situations in which the use of standard contrast cineangiography would be limited for some of the reasons noted previously. For example, we successfully used this method in a patient with severe heart failure who had suspected malfunction of prosthetic mitral and aortic valves in whom the physician caring for the patient believed that the use of contrast dye with its hemodynamic effects might be hazardous. Contrast media used in angiography causes peripheral vasodilatation, increased intravascular volume and increased cardiac output.[13] In patients whose left ventricular function is already compromised because of ischemic or valvular heart disease, these physiologic alterations may pose a significant clinical problem.[13] In addition, contrast-induced renal failure may be precipitated, particularly in patients with preexisting renal disease.[14] Finally, severe allergic reactions, although uncommon, may occur.[15] Thus, the use of contrast dye may not be desirable in some selected patients.

Another advantage of this technique is that multiple injections may be performed in different 2-D echocardiographic views to assess complex intracardiac flow patterns.[16] Cineangiography in these situations is limited by the dosage of contrast medium that may be used in an individual patient and by the overlapping of contrast-filled structures. The ability to repeat a large number of injections with contrast 2-D echocardiography also facilitates the assessment of MR when there are frequent premature ventricular contractions that may occur with injection of contrast media during left ventricular cineangiography. By comparison, spurious

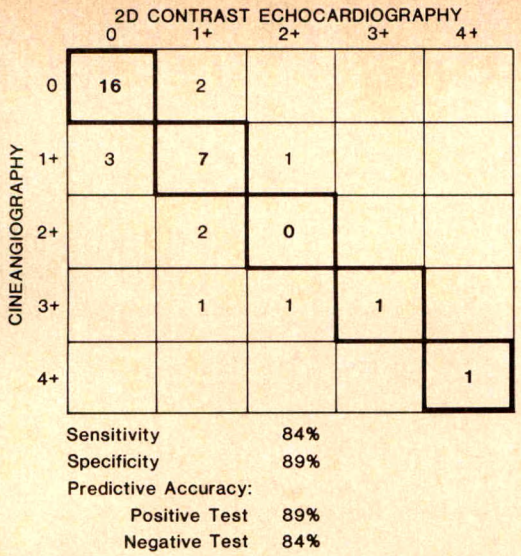

FIGURE 3. The semiquantitative assessment by contrast 2-dimensional (2D) echocardiography and cineangiography of mitral regurgitation.

MR due to premature ventricular contractions occurring spontaneously or, rarely, induced by the injection and irritation of the myocardium during contrast echocardiography is easily diagnosed; the injection is simply repeated after the contrast has cleared. (Once microbubbles appear in the left atrium it is difficult to assess further regurgitation during subsequent sinus beats until the chamber is again free of microbubbles.)

Finally, exposure to radiation can occassionally become a significant limitation to cineangiographic study as, for example, in pregnant patients, when adverse effects of the radiation to the fetus must be considered.[17,18] Contrast 3-D echocardiography during cardiac catheterization can be used to assess valvular lesions with minimal radiation exposure. Complete cardiac catheterization with hemodynamic data can thus be obtained that would facilitate appropriate management decisions during pregnancy.[18]

However, there are technical problems associated with 2-D echocardiography. The major problem is the inability to obtain adequate 2-D echocardiograms in all patients. We had an 11% incidence of inadequate studies from procedures performed during cardiac catheterization. A technically difficult study in the electrocardiographic laboratory before cardiac catheterization does not, however, necessarily preclude an adequate contrast study for valvular regurgitation. Multiple views may be used, including apical and subcostal views, to allow adequate visualization of the microbubbles. Often, a slightly "off-axis" view, which is inadequate for standard measurements or analysis, may still be used satisfactorily to visualize the regurgitant chamber being analyzed for microbubbles.

There are many causes of false-positive and false-negative studies with contrast 2-D echocardiography. The major problem is the presence of a high level of background noise that either prevents the detection of the microbubbles or may simulate their appearance. Often, microbubbles can be detected against a high level of background noise because of the characteristic movement pattern of the microbubbles. In 5 of our patients in whom 2-D echocardiography was incorrect in the detection of MR, the background noise was high and, in retrospect, 2 of these studies incorrectly read as negative had a few microbubbles seen in the left atrium. The 2 patients who had positive tests for MR by 2-D echocardiography that were negative by cineangiography were, in review, again read as positive; 1 patient, as mentioned previously, may have had acute, transient MR. However, it is also possible that the cineangiogram was not optimally positioned to detect a small amount of MR. Another cause of false-positive MR may be that which is induced by the catheter, and is therefore inconstant. False-negative studies by 2-D echocardiography might also be caused by a streaming or jet effect of the regurgitant lesion; therefore, we required that a negative visualization be present in at least 2 views in order to reduce this possibility. An inadequate injection of contrast would prevent adequate visualization of a contrast effect; therefore, it is important to be able to visualize the microbubbles at the site of injection. However, with aortic root injections, this was not possible in all patients; but in our study, we had no false-negative studies for AR. Improper placement of the catheter high in the aortic root may cause false-negatives for AR by either 2-D echocardiography or cineangiography and care should be taken to position the catheter properly. Five of the 7 studies graded as 4+ by 2-D echocardiography were graded 3+ by cineangiography. This discrepancy may reflect the tomographic nature of 2-D echocardiography. By sampling through a regurgitant jet (Fig. 1), the contrast may be detected at its earliest appearance, which is the major difference in the 2 grades. With cineangiography, the contrast may be diluted into a dilated left ventricle and, therefore, its detection delayed.

Visual assessment of the presence and severity of regurgitation is more difficult for MR than for AR, particularly if the left atrium is small and the regurgitation is mild. In our series, the difference in the severity of MR by the 2 techniques was >1 grade in only 1 patient. In AR, the correlation for grading of severity between contrast 2-D echocardiography and cineangiography was excellent ($r = 0.998$) and in no instance was the difference in grade >1. The visual grading scale that we devised for contrast echocardiography in the assessment of AR and MR is similar to the widely used grading assessment by contrast cineangiography and may, therefore, be easily adopted for this use.

Two-Dimensional Echocardiographic Determination of Right Atrial Emptying Volume: A Noninvasive Index in Quantifying the Degree of Tricuspid Regurgitation

NICHOLAS L. DePACE, MD, JIAN-FANG REN, MD, MORRIS N. KOTLER, MD, GARY S. MINTZ, MD, DEMETRIOS KIMBIRIS, MD, and PETER KALMAN, MD

Contrast echocardiography and inferior vena cava ultrasonography are useful techniques in diagnosing tricuspid regurgitation (TR) but are not helpful in estimating the severity. Using a computerized light-pen method for tracing the right atrial (RA) border during systole and diastole in the apical 4-chamber view, single-plane volume determinations were calculated in 10 normal subjects (Group I), 18 patients with atrial fibrillation (AF) and no TR (Group II), 14 patients with mitral stenosis and mild TR (Group IIIa), and 8 patients with mitral stenosis and severe TR (Group IIIb). TR was quantitated as absent, mild or severe by contrast right ventriculography. The RA end-systolic volume was 36.4 ± 13.1 ml in Group I patients, 59.1 ± 16.8 ml in Group II patients, 76.9 ± 55.4 ml in Group IIIa patients, and 154.6 ± 57.3 ml in Group IIIb patients (all Groups versus Group I, $p < 0.001$). The mean RA emptying volume, which equals RA end-systolic volume − RA end-diastolic volume, was 15.3 ± 5.0 for Group I, 17.7 ± 3.0 for Group II, 30.4 ± 8.0 for Group IIIa, and 71.6 ± 25.4 for Group IIIb. All 8 patients with severe TR but none of the 14 patients with mild TR had an RA emptying volume >40 ml ($p < 0.001$). In addition, all 28 patients in Groups I and II but only 4 of 14 patients in Group III had an RA emptying volume <26 ml ($p < 0.01$). The mean RA pressure measured at cardiac catheterization correlated with RA emptying volume ($r = 0.71$, $p < 0.001$). Thus, RA emptying volume is useful for separating severe TR from mild TR in patients with mitral stenosis.

(Am J Cardiol 1983;52:525–529)

The clinical determination of the severity of tricuspid regurgitation (TR) at the bedside is often difficult. In TR, M-mode and 2-dimensional (2-D) echocardiography produce a nonspecific pattern of right ventricular volume overload.[1,2] Using peripheral contrast injections of saline solution, blood or indocyanine green, microcavitations or bubbles can be seen moving back and forth from the right atrium into the inferior vena cava.[3] Although M-mode and 2-D echocardiography are valuable in diagnosing TR, its severity is usually not determined. Recently, real-time inferior vena cava ultrasonography was found useful in distinguishing patients with severe TR from those with normal or mild TR in 75% of subjects.[4] Although exaggerated left atrial expansion during ventricular systole has been described in patients with severe mitral regurgitation (MR),[5] right atrial (RA) expansion in patients with TR has not been studied. This report evaluated RA emptying volume in quantifying the degree of TR in patients with mitral stenosis.

Methods

Patients: The 2-D echocardiographic data in 50 patients form the basis of this report. The control group consisted of 10 consecutive patients; all had normal sinus rhythm with normal hemodynamic values, left ventriculography and coronary angiography at cardiac catheterization (Group I). Eighteen patients with atrial fibrillation (AF) without evidence of TR constituted Group II. Thirteen patients had coronary or hypertensive cardiovascular disease and 2 had dilated cardiomyopathy without valvular involvement. Three of the 18 patients had mitral stenosis without TR as determined by right ventriculography. Group III included 22 patients with pure rheumatic mitral stenosis (without MR); all had TR by contrast right ventriculography. All patients underwent complete left- and right-sided cardiac catheterization. The mitral valve area was calculated using the Gorlin formula.[6]

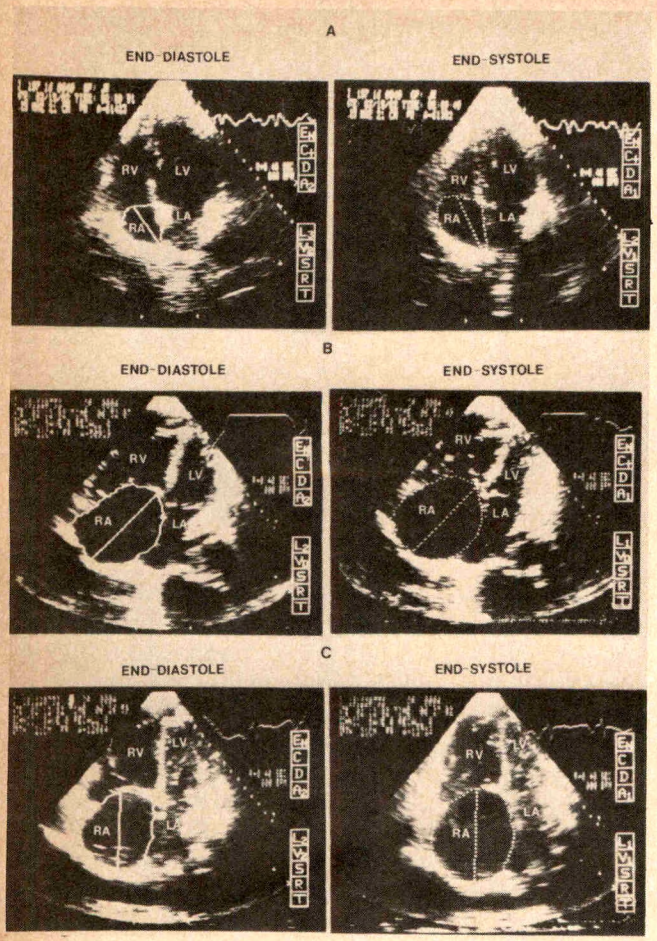

FIGURE 1. A, computerized light-pen method for tracing the right atrial (RA) border in the 4-chambered apical view in end-diastolic and end-systole in a normal control subject (Group I). The RA emptying volume is 14 ml. **B,** RA endocardial tracing in a patient with mild tricuspid regurgitation (Group IIIa). The RA emptying volume is 38 ml. **C,** RA endocardial tracing in a patient with severe tricuspid regurgitation (Group IIIb). The RA emptying volume is 80 ml. LA = left atrium; LV = left ventricle; RV = right ventricle.

Contrast right ventricular angiography was performed percutaneously by way of the transfemoral route with the patient in the right anterior oblique projection. TR was quantitated as absent, mild and moderate-severe (or significant). In mild TR, contrast material refluxed from the right ventricle into the right atrium at a point other than where the catheter crossed the tricuspid valve. In addition, the amount of contrast material refluxed was not enough to fully opacify the right atrium or any part of the vena cava. (TR only at the point where the catheter crossed the tricuspid valve was considered artifactual.) In moderate-severe TR, the right atrium was completely opacified or the venae cavae were partially opacified, or both.

Echocardiography: All patients were examined within 24 hours of cardiac catheterization by real-time cross-sectional echocardiography using a Varian V-3400 or V-3400 R phased-array sector scanner with a 2.25-MHz transducer. Echocardiograms were taken at 60 frames/s and recorded on videotape. Single images were photographed with a mounted Polaroid® camera. An electrocardiogram was recorded and displayed simultaneously to allow for timing of intracardiac events.

The right atrium was evaluated in the 4-chamber apical view. In all patients the ultrasonic transducer was positioned at the point of the maximal cardiac impulse and angled toward the right shoulder until an image was obtained that included all 4 cardiac chambers and both the mitral and tricuspid valves. Thereafter, the transducer was angled to obtain the maximal RA and right ventricular size while recording portions of both atrioventricular valves.[7] The modified 4-chamber view was chosen because it most clearly defines the RA border. In addition, dynamic RA motion can be evaluated in this view.

A computerized light-pen method for tracing the RA border was used. End-diastole was taken as the smallest RA dimension and end-systole as the largest atrial dimension (Fig. 1). Single-plane volume determination was made for both end-diastole and end-systole using the area-length method. The formula calculated for volume (V) is $8A^2/3$ L, where A = area and L = length.[8,9] We defined the emptying (or expansion) volume (RAEV) as end-systolic RA volume (ESV) − end-diastolic RA volume.

Expansion rate represented a measure of the rate of RA filling and was defined as expansion volume/expansion time. Expansion time represents the time from the onset of the QRS complex to the end of the T wave in seconds. RA ejection fraction was calculated as expansion volume/end-systolic volume.

All measurements were made during quiet respiration. In patients with AF, 4 consecutive representative cycles were analyzed and averaged. The cause of TR was considered organic if a thickened valve with restricted motion was noted on 2-D echocardiography. Normal-appearing tricuspid valve motion with good excursion of the individual leaflets indicated functional TR secondary to pulmonary hypertension. Echocardiographic measurements of RA volumes were performed independently in a blinded fashion without the knowledge of the angiographic findings. Intraobserver variation for 2-D echocardiographic RA volume determinations was 5.3%.

Statistical analysis: Statistical analysis was performed using the chi-square method, *t* test and analysis of variance and linear regression analysis when appropriate. The following definitions of statistical terms were used:

$$\text{Sensitivity} = \frac{\text{True positive (TP)}}{\text{true positive + false negative (FN)}} \times 100$$

$$\text{Specificity} = \frac{\text{True negative (TN)}}{\text{True negative + false positive (FP)}} \times 100$$

$$\text{Positive predictive value} = \frac{TP}{TP + FP} \times 100$$

$$\text{Negative predictive value} = \frac{TN}{TN + FN} \times 100$$

$$\text{Predictive accuracy} = \frac{TP + TN}{TN + FN + TP + FP} \times 100$$

Results

Study group: The 10 Group I patients consisted of 6 women and 4 men, aged 23 to 65 years. The 18 Group II patients consisted of 12 men and 6 women, aged 41 to 87 years. The 22 Group III patients consisted of 4 men and 18 women, aged 34 to 71 years. Nineteen Group III patients had AF and 3 were in sinus rhythm. Group III was subdivided into Group IIIa, which included 14 patients with angiographic mild TR, and Group IIIb, which included 8 patients with severe TR. Although the mitral valve area was smaller in Group IIIb than in Group IIIa patients, this difference was not significant (NS) (0.84 ± 0.34 cm^2 versus 1.17 ± 0.68 cm^2). The heart rate ranged from 54 to 98 beats/min.

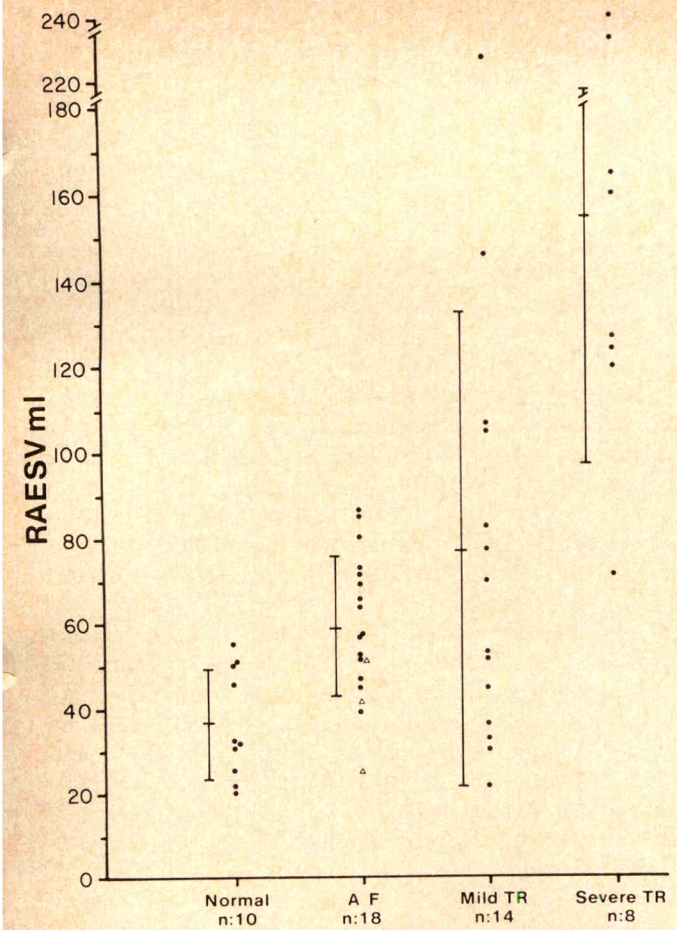

FIGURE 2. Right atrial end-systolic volume (RAESV) for the 4 groups of patients. **Bars** indicate the mean ± standard deviation. **Open triangles** indicate patients with mitral stenosis and no tricuspid regurgitation (TR) on right ventriculography. AF = atrial fibrillation.

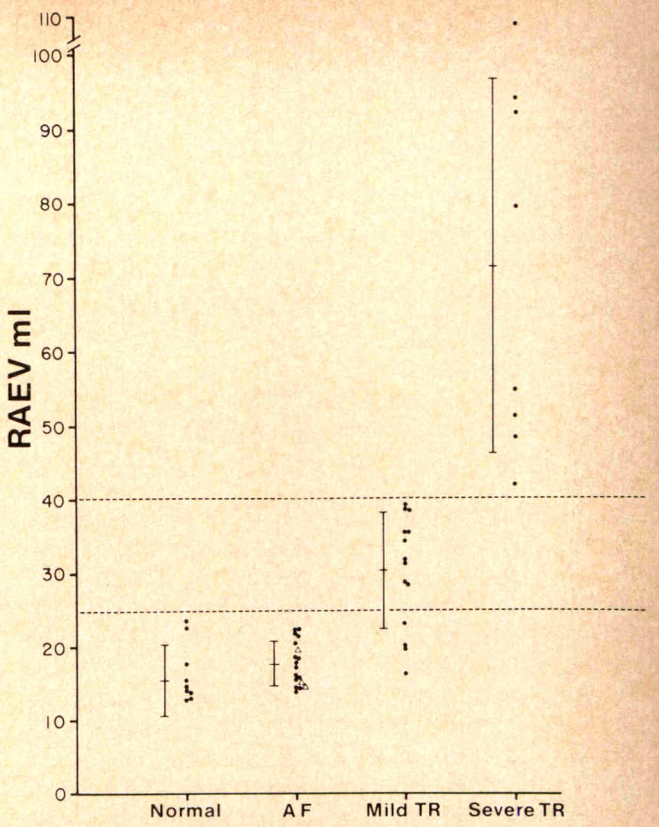

FIGURE 3. Right atrial emptying volume (RAEV) for the 4 groups of patients. **Open triangles** indicate patients with mitral stenosis and no tricuspid regurgitation (TR) on right ventriculography. AF = atrial fibrillation.

Right atrial volume dimensions: The mean RA end-systolic volume was similar for the 10 control patients with normal sinus rhythm (Group I) and the 18 patients with AF (Group II), but was significantly larger for the 22 patients with TR (Group III). The mean RA end-systolic volume was significantly larger in patients with severe TR (Group IIIb) than in those with mild TR (Group IIIa) ($p < 0.01$) (Fig. 2). Although the RA end-diastolic volume was larger in patients in Group IIIb than in patients in Group IIIa, this difference was not significant (82.9 ± 54 versus 47.4 ± 52 ml).

Right atrial phasic changes: The RA emptying volume was 15.3 ± 5.0 ml in Group I patients, 17.7 ± 3.0 ml in Group II patients and 45.4 ± 25.8 ml in the Group III patients. The RA emptying volume further separated patients in Group IIIa (mild TR) from those in Group IIIb (severe TR) (Fig 3). All 8 patients in Group IIIb had an RA emptying volume >40 ml, compared with none of the 42 patients in Group I, II or IIIa ($p < 0.001$). All Group I and II patients had an RA emptying volume <26 ml, whereas 10 of 14 Group IIIa patients had an RA emptying volume >26 ml ($p < 0.01$). Patients in Group II had a lower RA ejection fraction than patients in the other groups (Table I).

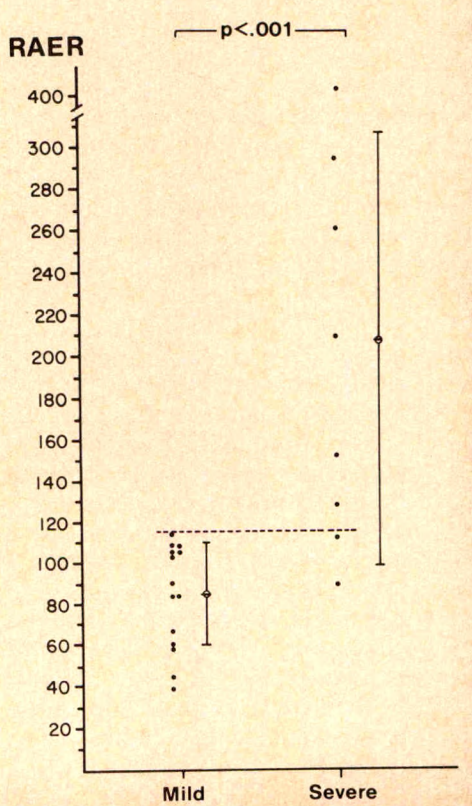

FIGURE 4. Right atrial expansion rate (RAER) in patients with mild and severe tricuspid regurgitation. See text for details.

TABLE I Two-Dimensional Right Atrial Indexes

	Cases	RAESV (ml)	RAEV (ml)	RAEF (%)	RAER (ml/s)
Group I	10	36 ± 13	15 ± 5	44 ± 14	39 ± 9
Group II	18	59 ± 17	18 ± 3	30 ± 9	–
Group IIIa	14	77 ± 55	30 ± 8	51 ± 19	84 ± 27
Group IIIb	8	155 ± 57	72 ± 25	50 ± 18	207 ± 108

RAEF = right atrial ejection fraction; RAER = right atrial expansion rate; RAESV = right atrial end-systolic volume; RAEV = right atrial emptying volume.

TABLE II Correlation of Right Atrial Emptying Volume With Presence of Tricuspid Regurgitation in Patients With Mitral Stenosis*

	Patients (n)	%
Sensitivity	18/22	82
Specificity	28/20	100
Positive predictive value	18/18	100
Negative predictive value	28/32	88
Predictive accuracy	46/50	92

* Right atrial emptying volume >26 ml.

The RA expansion rate similarly separated Group IIIb patients from Group IIIa patients (Fig. 4). None of the 14 Group IIIa patients and 6 of the 8 Group IIIb patients had a RA expansion rate >116 ml/s ($p < 0.001$).

Relation between mean right atrial and pulmonary pressure with right atrial emptying volume: The mean RA pressure corrected well with the RA emptying volume in the 36 patients who had RA catheterization measurements. The mean RA pressure ranged from 5 to 30 mm in the 24 patients with mitral stenosis (3 without and 21 with TR). The RA emptying volume correlated with mean RA pressure ($r = 0.71$, $p < 0.001$). Mean pulmonary artery pressure ranged from 11 to 68 mm Hg in Group III. There was no correlation between pulmonary artery pressure and RA emptying volume ($r = 0.06$).

Sensitivity, specificity and predictive accuracy differentiating severe from mild tricuspid regurgitation (Table II): The RA emptying volume was the most useful index in separating the 22 patients with pure mitral stenosis and TR from the 28 patients without TR. Using a value of 26 ml as a cut-off, a sensitivity of 82%, specificity of 100%, positive predictive value of 100%, negative predictive value of 88% and predictive accuracy of 92% was achieved in differentiating normal subjects from patients with mild TR. The RA emptying volume was useful in differentiating patients with severe TR from those with mild TR, with a sensitivity, specificity and predictive accuracy of 100% when a value of 40 ml was applied.

Discussion

The diagnosis of TR may be difficult by physical examination. Angiographic definition of TR is confusing because, depending on catheter position, factitious regurgitation may be produced. In addition, right ventricular angiography is invasive and not without risk to the patient. There appears to be no accepted standard for diagnosing TR.[10] Although contrast echocardiography may be useful in detecting TR, severe right heart failure, cardiac tamponade and arrhythmias may produce conflicting results.[3] Differentiating mild from severe TR is possible using inferior vena cava ultrasonography; however, differentiating normal subjects from patients with mild TR is not easy. Doppler echocardiography may offer an additional noninvasive approach to the diagnosis of TR and even allow its quantification.[11]

The present study describes the use of RA volumetric changes (the emptying volume) as a means of differentiating mild from severe TR. RA phasic changes may be more precise in assessing TR than inferior vena cava ultrasonography. This may be because the right atrium is the first reservoir that receives the regurgitant volume. Also, despite similar amounts of TR, a large, noncompliant right atrium may not transmit the reversal of flow into the vena cava as well as a small compliant right atrium.

Two-dimensional echocardiography is a good method of identifying the boundaries of the right atrium and measuring RA volume in almost all patients.[7] However, it is not the precise determination of RA volume measurement that is important, but rather, the phasic changes, which allow patients with TR to be differentiated from those without TR. Simply planimetering the RA area failed to differentiate these patients. There was no difference between patients with and those without AF with regard to RA emptying volume if TR was absent. Although right ventriculography was not performed in all patients, most Group I or II patients had normal clinical and physical examinations. The 3 patients with mitral stenosis in Group II who had no TR on right ventriculography all had an RA emptying volume of <20 ml.

There is considerable controversy over whether TR may be induced during AF. Ferrer et al[12] suggested that functional TR may be related to AF. The mechanism may be related to improper valve closure as a result of failure of the atria to contract before ventricular systole. However, recent work has shown no mitral and pulmonary venous regurgitation with AF in canine models.[13] Our studies show that AF is associated with a variable-sized right atrium but a small emptying volume. Therefore, the absent clinical, hemodynamic and right ventriculographic evidence of TR in these patients supports the concept that AF, as such, does not produce significant TR. This is in agreement with other investigators.[14] An increased RA emptying volume simply implies that there is additional contribution to inflow of the right atrium during systole. The fact that the RA ejection fraction was not increased in TR emphasizes that it is the magnitude of change in RA volume from diastole to systole that is representative of forward and retrograde flow into the right atrium during systole and not the ejection fraction.

This study has several limitations. First, the 22 patients with TR are a select group. They underwent right ventriculography because of suspected TR. Therefore, the sensitivity of our technique in predicting TR prospectively is not known. Second, patients with severe

MR have grossly enlarged atria that expand in systole. This may produce systolic bulging of the interatrial septum and, thus, affect the RA emptying volume. Third, problems are associated with using a light pen to calculate chamber volumes from stop-frame images. There is a parallax between the observed image on the curvilinear screen and the actual image. In addition, the endocardial borders, which seem obvious in real-time, may be indistinct in the stop-frame mode. Fourth, in cases of irregular AF with markedly irregular or slow rates (long-filling periods) or fast rates, representative cycles may not be available for computation. At least 4 consecutive beats should be analyzed and the mean value calculated.

Notwithstanding these limitations, the RA emptying volume is a useful 2-D echocardiographic measurement for detecting and quantitating the amount of TR that does not require intravenous contrast injections or contrast right ventriculography. AF appears to have little effect on RA expansion in the absence of TR.

Influence of Volume Loading on Intraoperative Hemodynamics and Perioperative Fluid Retention in Patients With Valvular Regurgitation Undergoing Prosthetic Replacement

J. GILBERT STONE, MD, PAUL F. HOAR, PhD, MD, and HOSHANG J. KHAMBATTA, MD

Preload and afterload were controlled intraoperatively in 2 groups of patients with valvular regurgitation and congestive heart failure in order to determine the effect of fluid loading on weight gain and subsequent recovery. As a part of their anesthetic management before cardiopulmonary bypass, 16 patients were given 1 liter of crystalloid with nitroprusside infused at 1 μg/kg/min and 16 received 4 liters of crystalloid with nitroprusside at 4 μg/kg/min. Arterial and filling pressures were kept the same in both groups. Heart rate and vascular resistance became significantly lower and cardiac index and stroke volume significantly higher in the fluid-augmented group. The transition to cardiopulmonary bypass was smoother for the fluid-augmented patients. All patients survived, and 2 in each group were ventilated beyond 24 hours. The mean weight gain at surgery was the same in the 2 groups (3 kg). For the first 2 postoperative days, body weight remained unchanged and thereafter, both groups lost weight at 0.6 kg/day. Preoperative weight was reached on day 7 and discharge occurred on day 15, 2 kg below control. Thus, a modest operative weight gain in these patients is inevitable, benign, and independent of the volume of fluid infused before bypass.

(Am J Cardiol 1983;52:530–533)

Sodium restriction and diuretics are a part of the medical management of patients with valvular regurgitation and congestive heart failure. Such therapy alleviates undesirable symptoms, but does so by reducing intravascular volume, often to the extent that an operative candidate comes to surgery in a relatively hypovolemic state.[1–3] For the patient with low-output failure, traditional anesthetic practice is to avoid fluid overload[4] and drugs that further depress the myocardium.[5] However, anesthetics without negative inotropic effects, such as narcotics or tranquilizers, fail to abolish the sympathetic response to surgical stimulation.[6] Peripheral vasoconstriction increases afterload, encourages regurgitant flow, reduces cardiac output and, in an already compromised heart, invites decompensation.[7] Vasodilators are used intraoperatively to overcome intense vasoconstriction;[6,8,9] but if intravascular volume has been depleted, capacitance vessels dilate, venous return decreases, and severe hypotension occurs before the beneficial effects of afterload reduction can be realized.[10] To maximize cardiac output and to provide a stable blood pressure during anesthesia and surgery, preload augmentation must accompany afterload reduction.[10,11] The postoperative consequences of fluid loading during surgery, however, remain undefined and of considerable concern. This study was undertaken to determine how patients with valvular regurgitation and heart failure would tolerate substantial intraoperative expansion of their intravascular volume.

Methods

Thirty-two patients (16 in each group) who underwent prosthetic valve replacement had been in chronic congestive heart failure, with a diagnosis of pure or predominant valvular regurgitation established at cardiac catheterization by angiography. In the fluid-restricted group, 8 patients had mitral regurgitation, 5 aortic regurgitation and 3 both lesions. There were 10 women and 6 men, mean age 55 years. In the fluid-augmented group, 7 patients had mitral regurgitation, 6 aortic regurgitation and 3 both. There were 9 men and 7 women, mean age 58 years. All patients had depressed left ventricular function, normal coronary arteries, and were in New York Heart Association functional classification III or IV. All were taking digitalis and diuretic preparations and were judged to be in optimal condition for their elective cardiac surgery. No

TABLE I Preinduction Control Hemodynamic Data

	Fluid-Restricted	Fluid-Augmented
Heart rate (beats/min)	77 ± 5	78 ± 4
Arterial pressure (mm Hg)	83 ± 3	85 ± 4
Vascular resistance (unit)	39 ± 4	38 ± 3
Cardiac index (liters/min/m^2)	2.1 ± 0.2	2.2 ± 0.1
Stroke index (ml/beat/m^2)	28 ± 3	31 ± 3
Wedge pressure (mm Hg)	17 ± 2	18 ± 2
Central venous pressure (mm Hg)	5 ± 1	5 ± 1

Values are mean ± standard error.
No significant difference between fluid-restricted and fluid-augmented groups in any variable.

TABLE II Hemodynamic Data During Surgery

	Fluid-Restricted	Fluid-Augmented
Fluid volume (liters, total)	1.0 ± 0.2*	4.2 ± 0.5
Nitroprusside rate (μg/kg/min)	1.1 ± 0.7*	4.1 ± 0.8
Heart rate (beats/min)	95 ± 6†	81 ± 4

one was medicated preoperatively with vasodilators. Patients were allowed their usual diets and fluid intake until midnight of the day before surgery.

Premedication consisted of intramuscular morphine, 3 to 10 mg, and scopolamine, 0.3 to 0.5 mg. Monitoring included a percutaneous 20-gauge radial artery catheter and a No. 7Fr triple-lumen thermodilution Swan-Ganz catheter. Pressure was directly measured with Statham P23ID transducers, continuously displayed on an oscilloscope, and recorded by a Hewlett-Packard 8-channel strip-chart recorder. Cardiac output was determined in triplicate with an Edwards Laboratory cardiac output computer (9250A). Awake, preanesthetic control measurements were made after steady-state conditions had been achieved (Table I). These included heart rate, systemic arterial mean pressure, right atrial pressure, pulmonary artery mean pressure, pulmonary capillary wedge pressure and cardiac output. Standard formulas were used to compute cardiac index, stroke volume index and systemic vascular resistance index.

Anesthesia was induced gradually over 10 minutes with morphine (1 mg/kg) and diazepam (0 to 0.3 mg/kg) and then maintained with nitrous oxide (0 to 50%) in oxygen. Nondepolarizing muscle relaxants were given, patients were intubated, and ventilation was controlled mechanically with the arterial carbon dioxide partial pressure kept at about 35 torr. After surgical stimulation began, nitroprusside (0.2%) was administered by infusion pump. Its rate varied with the expansion of the intravascular volume and was adjusted to maintain wedge pressure at the control level. The volume of intravenous fluid given over the 90-minute span from induction of anesthesia until the onset of cardiopulmonary bypass differed in the 2 groups. Patients in the fluid-restricted group received Ringer's lactate solution at 10 ml/kg/h and a consequent nitroprusside infusion rate of approximately 1 μg/kg/min. Patients in the fluid-augmented group received Ringer's lactate solution at 40 ml/kg/h in the same time frame; this necessitated a mean nitroprusside infusion rate of about 4 μg/kg/min. A second set of hemodynamic measurements was obtained during the relatively stable surgical period just preceding cardiopulmonary bypass (Table II). Up to that point, management of the patients in the 2 groups differed only in the rate of the nitroprusside infusion and the volume of crystalloid they had received.

The extracorporeal circulation was primed with 1,400 ml of Ringer's lactate solution, to which 35 g of dextrose and 300 ml of 25% salt-poor normal serum albumin had been added. When cardiopulmonary bypass was instituted, nitroprusside was discontinued and fluid administration was carried out by the pump team, which was unaware of the study and which responded in routine fashion to alterations in pressure and flow. After bypass, while hemostasis was being accomplished, all of the perfusate remaining in the pump was reinfused into the patient. Thereafter, fluid administration was determined by the clinical judgment of anesthesiologists and surgeons not involved in the study. Each patient was weighed preoperatively and then daily for 10 days after surgery with a bedside sling-type calibrated electronic scale (Scale-Tronics 2001). Weighings took place in the morning, and patients wore only their hospital gowns (all bottles, tubing and catheters were lifted from the litter). Postoperatively, digitalis was restarted early, vasodilators were rarely used, and diuretics were given at the discretion of the referring physician. Results were analyzed by paired and unpaired t tests. A p value < 0.05 was considered significant.

Results

The awake control measurements, obtained on the day of surgery just before induction of anesthesia, were essentially the same in the 2 groups (Table I) and corroborate our clinical impression that the groups were comparable. A low-output state was evident, and the effectiveness of the preoperative diuretic therapy was manifested by the low central venous pressure.

The hemodynamic consequences of differing fluid loads and differing nitroprusside levels during stable anesthesia and surgery shortly before bypass are listed in Table II. Arterial pressure was reduced about 10 torr from control in both groups. Vascular resistance decreased to normal in the fluid-augmented group; however, it could not be so lowered in the fluid-restricted group and remained elevated by about 25%. In this latter, relatively hypovolemic group, increasing the speed of the nitroprusside infusion beyond a mean of 1 μg/kg/min produced hypotension. With nitroprusside, with the arterial pressure at 71 ± 3 mm Hg and vascular resistance still elevated, the fluid-restricted patients continued to have a low cardiac index, a very diminished stroke volume index and tachycardia. Patients who were fluid-augmented tolerated more afterload reduction with nitroprusside and had an improved hemodynamic pattern. Although wedge pressure was the same in both groups and had not changed from control at the time of the second measurement, 3 more liters of crystalloid filled the expanded vascular space of the fluid-augmented patients. As a result, cardiac index and stroke volume index increased to reach normal levels and heart rate did not vary.

Despite stopping nitroprusside at the onset of dilutional, hypothermic cardiopulmonary bypass, hypotension (defined as arterial mean pressure < 50 mm Hg) occurred in 10 of the 16 fluid-restricted patients (Table

TABLE III Cardiopulmonary Bypass Comparisons

	Fluid-Restricted	Fluid-Augmented
Lowest arterial pressure (mm Hg) recorded in first 15 minutes of bypass	49 ± 3	64 ± 3
Supplemental crystalloid (ml) required to maintain bypass pressure and flow	680 ± 120	60 ± 3
Lowest hematocrit (%) on bypass	27 ± 1	22 ± 1
Urinary output (ml) from anesthetic induction until end of bypass	500 ± 80	1,500 ± 180

Fluid-restricted group always significantly different from fluid-augmented group ($p < 0.001$).

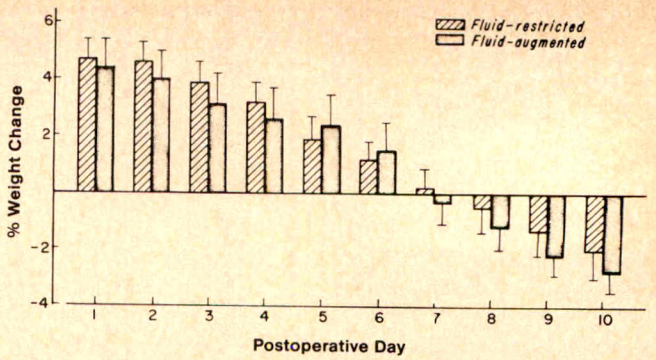

FIGURE 1. Postoperative body weight measured daily as a percent change from the preoperative value.

III). Pump flow was well maintained in all, and thus the pressure decrease was caused by a decrease in arterial vascular resistance. During the 10- to 15-minute equilibration period that followed the onset of bypass, vasopressors were given to 9 of the fluid-restricted patients, and a rapid infusion of Ringer's lactate solution was started in 14. In contrast, hypotension occurred and vasopressor therapy was instituted in 2 of the 16 fluid-augmented patients, with 3 receiving additional fluid loading. Hematocrit, obtained preoperatively and again after stabilization on bypass, decreased more in the fluid-augmented patients, 41 to 22% versus 40 to 27%. Urinary output from the start of anesthesia until the end of bypass was 1,500 ml in the fluid-augmented group and 500 ml in the fluid-restricted group.

All patients were ventilated postoperatively for at least 12 hours. Two patients in each group required ventilatory support for 2 days, but none became hypoxic or had evidence of more than minor pulmonary congestion.

Every patient in both groups gained weight at surgery. Postoperative body weights are depicted in Figure 1 as a percent change from the preoperative value. On no day were the mean weights of the 2 groups different. Mean weight gain at surgery averaged 3 kg and was the same in the 2 groups. For the first 2 postoperative days, body weight remained unchanged. Thereafter, body weights decreased steadily, and the rate of weight loss was the same in both groups. Patients lost about 0.6 kg/day. In both groups, preoperative body weight was reached on the seventh postoperative day. Patients were discharged on the fifteenth postoperative day in both groups; when they left the hospital, their weight was about 2 kg below control.

Discussion

We believe it is justified to conclude that operative weight gain is inevitable in these patients and the amount gained is independent of the volume of fluid infused before bypass. Patients with congestive heart failure did tolerate large intravenous fluid loads as a part of their anesthetic management, and neither intraoperative nor postoperative volume overload occurred in any of the fluid-augmented patients. In fact, it was the fluid-restricted patients who required intervention. In that group during cardiopulmonary bypass, the reservoir of the extracorporeal circulation became depleted, arterial pressure decreased, and volume supplementation was necessary for circulatory support.

Chronic preoperative diuretic therapy renders the ambulatory patient with congestive heart failure less dyspneic and more comfortable, but it does so by reducing the blood volume to a relatively depleted state, and thus by further decreasing cardiac output.[12] In response, there is a concomitant increase in circulating vasoactive substances and vascular resistance which tends to keep arterial pressure within normal limits.[12] Unfortunately, anesthetics and noxious surgical stimuli make vascular tone highly labile and thus disrupt the tenuous hemodynamic balance achieved in these patients by careful preoperative medical management. Cardiopulmonary bypass is an abrupt and even more extreme circulatory alteration. On the one hand, blood flow is mechanically maintained above that necessary to fulfill oxygen requirements. Edema fluid is mobilized from congested tissues and urinary output increases. On the other hand, body temperature is acutely lowered, severe dilutional anemia occurs and the lungs are excluded from the circulation. Initially, vascular tone decreases to a subnormal level,[13] arterial pressure falls, and a new relation forms between circulating blood volume and intravascular space. Later, especially with rewarming on bypass, catecholamines and other vasoactive substances are released increasing blood levels by several-fold.[13,14] Vascular resistance again becomes excessive, arterial pressure increases, and vasodilators are often indicated to improve the circulation and permit weaning from bypass.[14] In the immediate postoperative period after valve replacement, cardiac output remains low, often requiring support,[15] and only gradually improves over the succeeding months.

The question of how best to support a sagging and unstable circulation has intrigued clinicians since intervention became possible. Today in the acute-care setting, vasodilators have become prominent in the therapy of cardiac failure;[7] for not only is the circulation improved, but myocardial oxygen consumption does not increase.[12] However, vasodilators alone may not provide sufficient cardiovascular support, and then one must choose additional therapy. As a measure of the cost of intervention, Sarnoff et al[16] demonstrated that much

more myocardial energy was expended doing pressure as opposed to flow work. Preload augmentation can triple cardiac output and stroke work with only a minor increase (23%) in myocardial oxygen consumption.[17] Alternatively, catecholamines and other inotropic agents, which increase contractility and often afterload and heart rate as well, profoundly increase myocardial oxygen consumption.[12]

In conclusion, we have shown that intraoperative regulation of preload and afterload can effectively and safely enhance cardiac function in patients with heart failure. However, instead of acute intraoperative fluid loading, we suggest that expansion of the intravascular volume be attempted preoperatively, when patients can be gradually changed from a regimen of diuretics and sodium restriction to one of oral vasodilators and rehydration. Oral vasodilators have been somewhat of a disappointment as long-term therapy for cardiac failure because the initial improvement often wanes with time;[18,19] but perhaps in the immediate preoperative period they can be used to real advantage by facilitating the inevitable increase in blood volume that accompanies surgery.

Mitral Valve Prolapse Syndrome: Analysis of 62 Patients Aged 60 Years and Older

ALBERT J. KOLIBASH, MD, CHARLES A. BUSH, MD, MARY BETH FONTANA, MD, JOSEPH M. RYAN, MD, JAMES KILMAN, MD, and CHARLES F. WOOLEY, MD

Sixty-two patients diagnosed as having mitral valve prolapse, 60 to 81 years old, presented with disabling chest pain (20), symptoms of arrhythmias including palpitations and syncope (16), or mitral regurgitation (MR) with symptoms of congestive heart failure (26). The diagnosis of MVP was made on the basis of a combination of classic auscultatory, echocardiographic and angiographic findings. Thirteen of the 20 patients with chest pain had normal coronary angiograms and 7 had significant coronary artery disease (CAD). Patients with CAD could not be differentiated by clinical presentation alone. Furthermore, the incidence and types of arrhythmias, the presence of a positive stress test, and hemodynamic findings were similar in all patients in this group whether or not CAD was present. The 16 patients with palpitations had a broad spectrum of rhythm disorders, including both supraventricular and ventricular arrhythmias. Two patients had prehospital "sudden death" and 2 others had systemic emboli. Twenty-one of the 26 patients with MR had valve surgery. Intraoperatively the valves were described as enlarged, floppy and with redundant leaflets. Histologic examination showed extensive "myxomatous" changes throughout the valve leaflets.

Thus, mitral valve prolapse is a cause of symptomatic heart disease in the elderly. It has a predictable pattern of clinical presentation and should be considered in the differential diagnosis of older patients with disabling chest pain and arrhythmias and as the cause of progressive or severe MR.

(Am J Cardiol 1983;52:534–539)

Mitral valve prolapse (MVP), a well described clinical entity with characteristic auscultatory, echocardiographic and angiographic findings, usually becomes clinically manifest in the third through the fifth decades of life.[1–9] Most patients initially present with symptoms of chest pain and palpitations.[2,3,6] MVP is also a very common cause of clinically recognizable mitral regurgitation (MR) murmurs, which are usually preceded by nonejection systolic clicks.[3,5,6] Based on surgical and postmortem examinations, the primary pathologic process of MVP has been attributed to myxomatous degeneration of the mitral valve leaflets.[7–10] Although the prognosis in the majority of patients with the MVP has been described as good,[11–14] the long-term natural history of the MVP is not well defined, and few studies have directly addressed the presence and clinical presentation of patients with MVP who are ≥60 years.[15,16]

From the Divisions of Cardiology and Cardiovascular Surgery, the Ohio State University Hospitals, Columbus, Ohio. Manuscript received April 12, 1983; revised manuscript received May 16, 1983, accepted May 17, 1983.

The purpose of this study was to define the clinical spectrum of patients with MVP in the seventh through ninth decades of life and to gain a greater insight into the natural history of MVP.

Methods

All patients were ≥60 years old. The diagnosis of MVP was based upon auscultatory findings of midsystolic clicks or late systolic or holosystolic murmurs with typical postural variations,[4,16,17] M-mode echocardiographic findings of mid- to late posterior motion of the posterior mitral valve leaflet in systole,[7] and left ventricular angiographic presence of systolic posterior excursion of the mitral valve leaflets beyond the mitral valve annulus.[3,8,18] Each patient had at least 2 of these findings.

Sixty-two patients, aged 60–81 years, were included in this study. All patients were evaluated at University Hospital because of debilitating cardiac symptoms, which included 20 patients (15 women, 5 men) with disabling chest pain, 16 patients (12 women, 4 men) with symptoms suggestive of arrhythmias and 26 patients (16 men, 10 women) with symptoms of congestive heart failure and the murmur of MR. Fifty-two patients had technically adequate M-mode echocardiograms. Fifty-six patients underwent cardiac catheterization including coronary angiography. Significant coronary

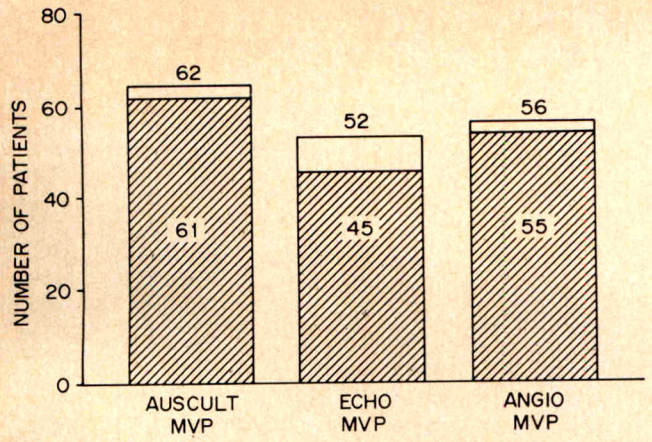

FIGURE 1. The sensitivity of the individual methods used to diagnose mitral valve prolapse (MVP). The number of patients with satisfactory examinations is listed at the top of each bar. The number of patients in whom the examination indicated MVP is listed in the shaded area of the bars. Angio = left ventricular angiography; auscult = auscultatory exam; echo = echocardiography.

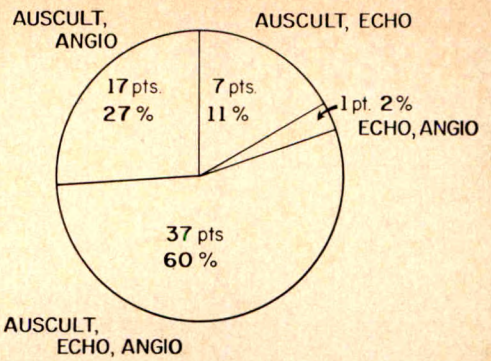

FIGURE 2. The basis for the diagnosis of mitral valve prolapse (MVP) and the number of patients in whom each of the diagnostic methods indicated MVP. Thirty-seven patients (60%) had evidence of MVP by all 3 examinations, whereas the diagnosis of MVP in 25 patients (40%) was based on a combination of 2 of the 3 methods that indicated MVP. Angio = left ventricular angiography; auscult = auscultation; echo = echocardiography.

artery disease (CAD) was defined as >50% transluminal narrowing of at least 1 major coronary vessel.

Results

Diagnosis: The 62 patients included 25 between the ages of 60 and 64 years old, 22 between 64 and 69 years, 6 between 70 and 74 years and 9 ≥75 years. These patients represented 4% of all adult patients who underwent cardiac catheterization in our laboratories during the study period.

The results of the auscultatory findings, echocardiography and left ventricular angiography are shown in Figure 1. The cardiac physical examination was abnormal in 61 of 62 patients. Auscultatory findings in the 36 patients with chest pain and symptoms of arrhythmias included 30 with mid- to late systolic murmurs associated with nonejection clicks and 5 with midsystolic clicks without murmurs. All 26 patients with congestive heart failure symptoms had a holosystolic murmur of MR.

Echocardiography demonstrated MVP in 45 of the 52 patients who had adequate M-mode echocardiograms. Angiographic prolapse was identified in 55 of the 56 patients who underwent cardiac catheterization; 44 had angiographic MR. Thirteen of the 56 patients also had evidence of significant CAD.

The combination of abnormal auscultatory, echocardiographic and angiographic findings is shown in Figure 2. Thirty-seven patients had MVP by auscultation, echocardiography and left ventricular angiography; 17 by auscultation and left ventricular angiography; 7 by auscultation and echocardiography; and 1 by echocardiography and left ventricular angiography.

Patients with mitral valve prolapse and chest pain: Twenty patients with MVP presented with disabling chest pain as their primary complaint, only 1 of whom had a history of a myocardial infarction. The average age was 64 years (range 60 to 82) and the average duration of symptoms was 4 years. All patients had coronary angiography, and the angiogram demonstrated CAD in 7. The resting electrocardiograms in the 13 patients without CAD revealed that 3 patients had left anterior hemiblock, 1 intraventricular conduction delay, 2 subendocardial ischemia, 2 nonspecific ST changes and 2 premature ventricular contractions (PVCs); 3 patients had normal electrocardiograms. Of the 7 patients with CAD, 2 showed left anterior hemiblock, 2 subendocardial ischemia, 1 inferior infarction and 1 nonspecific ST changes; 1 patient had a normal electrocardiogram.

Adequate treadmill stress tests were obtained in 7 patients; 4 indicated ischemic ST-segment changes, defined as >1 mm of ST-segment depression 0.08 second after the J point. Two of these 4 patients had CAD.

Twenty-four-hour Holter monitoring in 7 patients without CAD showed arrhythmias in all 7 patients, including paroxysmal atrial fibrillation in 1, rare PVCs in 1 and frequent PVCs (>10/minute) in 4, including ventricular bigeminy and ventricular tachycardia. Ambulatory monitoring in 3 patients with CAD disclosed premature atrial contractions (PACs) in 1, atrial fibrillation in 1 and rare PVCs in 1.

Echocardiographic MVP was seen in 14 of the 17 patients, 9 of 11 without and 5 of 6 with CAD.

Catheterization data for these patients with chest pain are shown in Table I. The data were remarkably

TABLE I Catheterization Data From Patients With Chest Pain

	All Patients (n = 20)	No CAD (n = 13)	CAD (n = 7)
Ejection fraction	69%	69%	70%
LVEDV (ml/m^2)	70	72	67
Post-angio LVEDP >24 mm Hg (no. of pts)	12	7	5
Angiographic MVP (no. of pts)	20	13	7

CAD = coronary artery disease; LVEDP = left ventricular end-diastolic pressure; LVEDV = left ventricular end-diastolic volume; MVP = mitral valve prolapse.

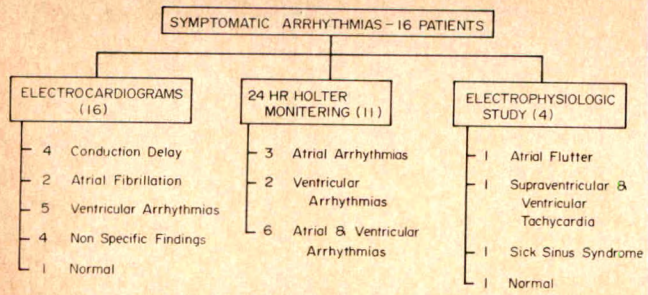

FIGURE 3. The methods used to identify the rhythm disorders in the 16 patients with palpitations and syncope and the type of arrhythmias.

similar whether or not CAD was present. Of the 7 patients with CAD, 1 had 1-vessel, 4 had 2-vessel and 2 had 3-vessel disease.

Patients with mitral valve prolapse and symptoms of arrhythmias: Sixteen patients presented with symptoms suggestive of arrhythmias, including 11 with palpitations and 5 with syncope. None of these patients had a history of a myocardial infarction. The average age of these patients was 66 years and the average duration of symptoms was 12 years. Two patients had clinical evidence of systemic emboli, both with visual blurring, visual field defects, atrial fibrillation and no evidence of cerebrovascular disease. Two of the 5 patients with syncope required cardiopulmonary resuscitation.

The diagnoses of the specific types of arrhythmias shown in Figure 3 were made from the resting electrocardiogram, 24-hour Holter monitoring or electrophysiologic studies. The resting electrocardiograms were abnormal in 15 patients. The ventricular arrhythmias seen on the electrocardiograms included ventricular tachycardia in 1 patient, frequent PVCs of >10/min in 2 patients and occasional PVCs in 2.

Twenty-four-hour Holter monitoring in 11 patients revealed supraventricular arrhythmias in 3, including paroxysmal atrial fibrillation, frequent PACs and paroxysmal supraventricular tachycardia. Two patients had ventricular arrhythmias alone identified as frequent PVCs. Six patients demonstrated both supraventricular and ventricular arrhythmias, which included sinus node arrest with frequent PVCs in 1, frequent PACs with frequent unifocal PVCs in 2, supraventricular tachycardia and frequent PVCs in 2 and ectopic atrial rhythm with multifocal PVCs in 1.

Four patients had electrophysiologic studies: 1 who developed atrial flutter when stimulated with PACs, 1 who developed both supraventricular and ventricular tachycardia and 1 who had significant sinus node disease; 1 showed no abnormalities.

Ten patients had cardiac catheterization and coronary angiography. Two patients had 1-vessel CAD. The average ejection fraction of all 10 patients was 64% and the left ventricular end-diastolic volume index was 70. The postangiographic left ventricular end-diastolic pressure was abnormally increased in 5 patients, with values of 24 to 36 mm Hg. Angiographic MVP was demonstrated in 9 of the 10 patients.

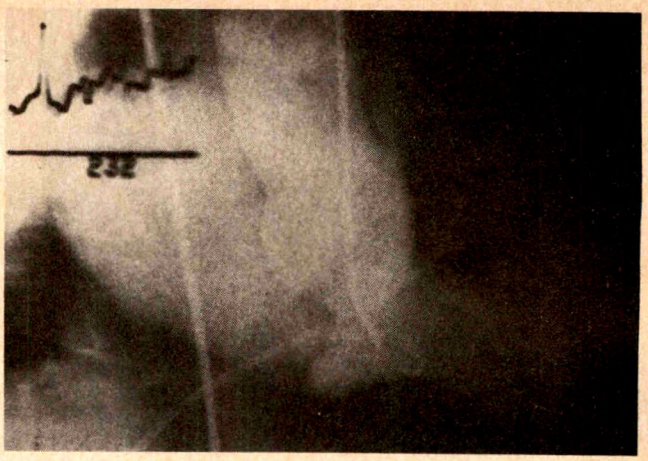

FIGURE 4. Thirty-degree right anterior oblique left ventriculogram, which demonstrates significant angiographic mitral regurgitation secondary to a prolapsing mitral valve with ruptured chordae. The ruptured chordae cannot be seen in this view. The left atrium is considerably enlarged.

Patients with mitral regurgitation and congestive heart failure: Twenty-six patients had significant MR and symptoms of congestive heart failure. The mean age of these patients was 68 years (range 60 to 81). Twenty-two of the 26 had a history of a heart murmur. Twelve patients had murmurs detected before age 30 years, 7 patients at 31 to 60 years and 3 patients above age 60 years.

Of these 26 patients, 20 had radiographic cardiomegaly. The resting electrocardiograms were abnormal in 25 patients; the most common abnormality was atrial fibrillation, which was seen in 13 patients. Five patients also had electrocardiographic criteria of left ventricular hypertrophy. Thirteen of 24 patients with adequate echocardiograms had MVP and 5 others had a flail mitral valve leaflet in addition to MVP.

The results of cardiac catheterization performed in all 26 patients are shown in Table II. Angiographic MVP with MR was seen in all 26 patients. Tricuspid valve

TABLE II Catheterization Data From Patients With Mitral Regurgitation

Hemodynamic Data	All Pts (n = 26)	MVR (n = 21)	No MVR (n = 5)
Ejection fraction	67%	68%	63%
LVEDV (ml/m^2)	119	125	90
Post angio LVEDP >24 mm Hg (no. of pts)	12	9	3
PCW pressure (mm Hg)	18	19	11
V wave (mm Hg) in PCW	34	38	20
Left and right ventricular angiography (no. of pts)			
MR	26	21	5
MVP	26	21	5
TVP	6/12	6	0
Coronary angiography (no. of pts)			
No CAD	22	17	5
CAD	4	4	0

CAD = coronary artery disease; MR = mitral regurgitation; MVR = mitral valve replacement; PCW = pulmonary capillary wedge; TVP = tricuspid valve replacement.

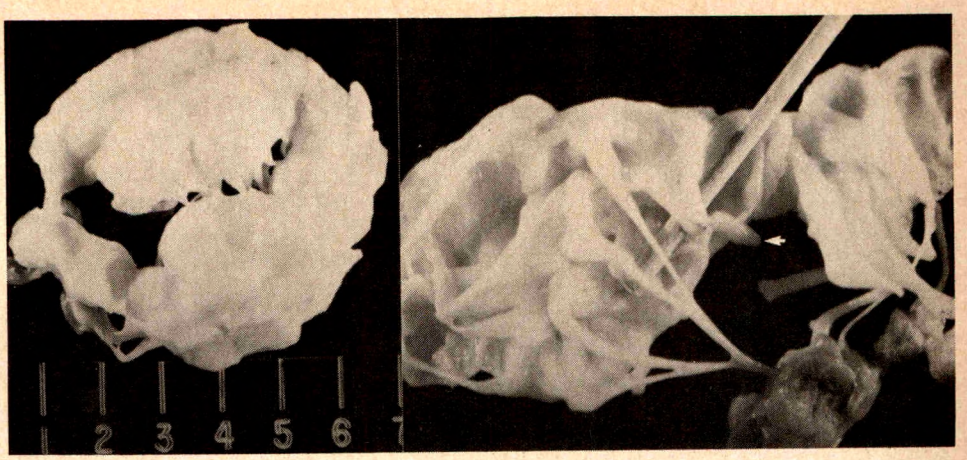

FIGURE 5. Left, The gross appearance of an abnormally large floppy valve with redundant leaflets as seen from the atrial side. The diameter and cross-sectional area of the valve are abnormally increased. **Right,** the same valve as seen from the ventricular side, again demonstrating the redundancy of the leaflets. The presence of several ruptured chordae are also seen (**arrow**).

prolapse was demonstrated in 6 of the 12 patients who had a right ventricular angiogram. Four patients had CAD, but none had a totally occluded vessel and none had evidence of a previous myocardial infarction.

In 21 patients, progressive clinical deterioration due to MR was so severe that cardiac surgery was performed. Table II lists the hemodynamic and angiographic data in these patients. Figure 4 shows the angiographic appearance of a severely regurgitant prolapsing mitral valve.

Three patients had additional cardiac surgery, including 1 who had aortic valve replacement for aortic insufficiency and 2 coronary artery bypass grafts. Two patients died postoperatively, 1 from congestive heart failure and 1 from sepsis. All surviving patients were significantly improved symptomatically at the time of hospital discharge and were in New York Heart Association functional class I or II.

Pathologic observations of the mitral valve in operative patients: All surgically excised mitral valves were described by the surgeon as floppy with redundancy of the valve leaflets. A flail leaflet was present in 11 patients. Pathologic examinations performed on 19 of the 21 valves revealed enlarged anterior and posterior leaflets and an enlarged mitral valve diameter, which averaged 4.5 cm for all valves. Figure 5 demonstrates the gross pathologic findings of a severely myxomatous valve. This valve is the same valve shown angiographically in Figure 4. The histologic findings of all valves included severe myxomatous changes with disarray of collagen. Such changes were extensively present throughout the valve leaflets and, in the majority of instances, also involved the chordal structures. The gross morphologic and histologic changes are very similar to those described in a recent study from this institution that involved surgically excised valves from patients with symptomatic MR.[19]

Discussion

The occurrence, frequency and clinical characterization of MVP in elderly patients has not been well defined. The present study identified MVP as a cause of symptomatic heart disease associated with significant morbidity in elderly patients who presented in a clinically predictable pattern with disabling chest pain, symptomatic arrhythmias and MR with congestive heart failure.

The reported prevalence of MVP in young women is 6 to 17%, based on auscultatory and M-mode echocardiographic findings.[20,21] Several postmortem studies have reported prevalence rates of 1 to 5% in older patients.[22,23] Pomerance[10] reported 35 cases of mucoid degeneration of the mitral valve in 3,083 adult necropsies and described similar changes in 4.5% of elderly patients with systolic murmurs.[22] Davies et al[23] reported that the overall incidence of severely floppy mitral valves was 4% in men and 5% in women in 1,984 routine hospital necropsies.[23] These severely floppy valves were not apparent until after age 40 years, and the incidence of severely floppy valves increased with age. The findings of Davies et al are consistent with the incidence of MVP (4%) seen in patients >60 years who underwent studies in our catheterization laboratories.

The results of our clinical study extend the necropsy findings of Pomerance[10] and Davies et al[23] by providing further evidence for MVP as a cause of symptomatic cardiovascular disease in elderly patients. Two additional studies also considered the occurrence of the MVP in the elderly. Tresch et al[15] reported 40 patients >60 years with echocardiographic evidence of MVP. Twenty-nine presented with cardiac symptoms of chest pain, palpitations or congestive heart failure. Higgins et al[16] described clinical findings in 40 men ≥50 years with echocardiographic MVP and with symptoms of chest pain and palpitations. Nineteen had arrhythmias and 21 left ventricular hypertrophy. Neither of the above studies provided information about hemodynamics nor the presence or absence of coronary disease; however, the clinical findings were very similar to those of patients in our study. It should be emphasized that our study is not a natural history study, but a study that defines a group of symptomatic elderly patients with auscultatory, echocardiographic and angiographic findings similar to those found in younger patients with MVP. Whether these older patients represent a progression of MVP with aging cannot be stated with certainty. However, several important aspects of our study deserve further emphasis.

Mitral valve prolapse and chest pain: Approximately one third of our patients presented with disabling chest pain, a well described symptom in younger patients with MVP.[2,3,6] Coronary angiography identified 7 patients with significant CAD, none of whom had left ventricular wall motion abnormalities or a history of myocardial infarction. Because the clinical presentation and laboratory data were remarkably similar in the patients with chest pain whether or not CAD was present, patients with CAD could be accurately identified only by performing coronary angiography.

The coexistence of MVP and CAD in the same patients has been described,[24] and CAD has been implicated as a cause of MVP. Although the cause of the MVP in our patients with CAD cannot be definitely established, this group of patients does point out problems in the differential diagnosis of chest pain in the elderly and emphasizes the necessity of thorough clinical evaluation.

Mitral valve prolapse and arrhythmias: Fifteen patients presented initially with symptoms suggestive of arrhythmias, a common finding in younger patients with MVP.[25] The diagnosis of these rhythm disorders was usually apparent from the resting electrocardiogram, 24-hour Holter monitoring or electrophysiologic studies. The types of rhythm disturbances were similar to those reported to occur in patients with MVP.[25] Of particular note are the 2 patients who survived sudden death, both of whom had normal coronary artery anatomy. Sudden death is rare, but has been reported to occur with MVP.[26]

Although multiple causes of arrhythmias exist in this age group, MVP was considered a likely cause of arrhythmias in our patients, particularly in the absence of other definable types of heart disease. Neither of the 2 patients with 1-vessel coronary disease had angina or had sustained a previous myocardial infarction, and none of the 5 patients without catheterization studies had chest pain.

Two patients in this group and another patient in the chest pain group had clinical findings consistent with systemic embolization. The presence of atrial fibrillation in 2 of our 3 patients introduces another potential factor. The association between MVP and systemic embolization has been recognized; however, this relationship is unclear.[27]

Mitral valve prolapse, mitral regurgitation and mitral valve replacement: The 26 patients with the murmur of MR and symptoms of congestive heart failure may contribute to the understanding of the natural history of MVP in a select group of patients. A history of a heart murmur in 22 of these patients, and particularly in the 12 patients who had a known heart murmur before age 30 years, suggests that a less severe abnormality of the mitral valve existed throughout their earlier years. The presentation of these patients at an older age with congestive heart failure and clinically recognizable MR suggest that this "benign" mitral valve abnormality progressed to a severe lesion with aging. These observations imply that the natural history of MVP in certain patients may include progression to clinically significant MR.

Several additional clinical findings in these patients with MR must be emphasized, including the high incidence of atrial fibrillation, the coexistence of tricuspid valve prolapse, the low incidence of CAD and the male predominance among patients who received mitral valve surgery. Atrial fibrillation was very common in the patients who presented with congestive heart failure and severe MR (13 of 26 patients). This rhythm disturbance also occurred frequently in the studies of Higgins et al[16] (14 of 40 patients) and Ranganathan et al[18] (11 of 16 patients). Atrial fibrillation may have contributed in part to the sudden clinical deterioration in many of these patients.

The association of tricuspid valve prolapse with MVP is well known[28] and implies multivalvular involvement in patients with MVP. However, the predominant hemodynamic lesion in our patients was MR and the degree of tricuspid regurgitation was only mild to moderate.

CAD was not an important factor in the clinical presentation of these patients, since the incidence of CAD was low and none of the patients with CAD had chest pain or evidence of a myocardial infarction. Cardiac catheterization data indicated excellent left ventricular function in the overall group, although the left ventricular end-diastolic volumes were abnormally increased, as might be expected.

The incidence of MVP is significantly higher in the female population in the younger age group.[2,6] This female preponderance also occurred in our patients with chest pain and arrhythmias. However, this sexual preponderance was reversed in the group with severe MR.

The pathologic findings of extensive myxomatous changes in the surgically excised mitral valves in our patients are important relative to necropsy studies of mitral valves.[10,23,29] Nonspecific myxomatous changes in the mitral valve leaflets occur with aging, but are usually minor and not clinically significant.[23,29] The incidence of extensive myxomatous changes that involve the mitral valve in older patients is low, and such changes are unlikely to be the result of aging alone.[29] Furthermore, Davies et al[23] showed that severely floppy valves were direct causes of death and that patients with such valves were highly likely to have had a known heart murmur many years before their deaths.[23]

Severe myxomatous changes in mitral valves excised from 12 patients, mean age 51.5 years, have been reported from our laboratory.[19] Those valves were clearly differentiated from control valves on the basis of increased surface area, increased diameter and decreased density of the affected valve. Histologically, these valves showed more extensive myxomatous changes and, more specifically, collagen dissolution. The pathologic studies of Pomerance,[10,29] Davies et al[23] and King et al[19] further suggest that severely myxomatous mitral valves represent progressive disease of the valve rather than a process that occurs naturally with aging.

Such pathologic studies are of great clinical relevance because myxomatous mitral valves that produce severe MR have become one of the more common indications for mitral valve surgery in the elderly patient. Such observations are supported by several pathologic studies of surgically excised mitral valves that are characterized by extensive myxomatous changes.[9,23,28,30,31] Particularly noteworthy are the studies of Davies et al,[23] who found such changes in 44 valves, and Salamon et al,[30] who replaced 66 myxomatous mitral valves in patients whose average age was 58 years. Thus, the results of our study add a clinical dimension to the surgical pathologic studies and confirms the presence of severe myxomatous mitral valve disease that causes severe MR in older persons.

Implications of mitral valve prolapse with respect to natural history: The results of this study should not be interpreted as a true reflection of the natural history of patients with MVP. Nevertheless, there is accumulating evidence that MVP is an entity to be considered as a cause of symptomatic heart disease in the elderly patient. The necropsy studies of Pomerance[10,22,29] and Davies et al,[23] as well as the study of King et al,[19] this study, and other clinical studies identifying the MVP in elderly patients[15,16] and the pathologic findings of surgically excised myxomatous valves,[28,30,31] may have important implications with respect to the natural history of the MVP.

Heretofore, natural history studies have emphasized the benign nature of MVP.[11–14,32] Although it seems justifiable to consider MVP as benign and to reassure patients that their prognosis is good, the many reports in the literature about the benign course of MVP are unsupported by long-term data. MVP carries a significant morbidity in an as yet undetermined number of patients. In a study of 62 patients by Allen et al,[12] 3 patients died of cardiac-related causes. Mills reported 8 complications in 53 patients, 2 of whom died suddenly and 5 of whom developed progressive MR.[13] Koch and Hancock[32] followed 40 patients for 10 years and reported 5 patients with sudden death, 2 with congestive heart failure and 1 patient with chronic atrial fibrillation.[32] Numerous investigators have also reported complications such as sudden death,[2,6,26] bacterial endocarditis[12,13] and severe MR requiring mitral valve replacement[9,13,18,28,30,31] in patients with MVP. Particularly noteworthy in this regard are 2 studies, a recent report by Clemens et al,[33] who reemphasized the importance of bacterial endocarditis as a complicating factor with MVP, and the necropsy findings of Davies et al,[23] who implicated severely floppy mitral valves as a direct cause of death from bacterial endocarditis and severe MR.

The results of our study indicate that certain patients with MVP may be at risk later in life of developing complications such as disabling chest pain, cardiac arrhythmias, arterial emboli or progressive MR with congestive heart failure requiring consideration for mitral valve surgery. There is a gap in our understanding of the pathogenesis and natural history of this entity, and we cannot identify younger patients who may be likely to develop complications later in life.

Value of Isometric Exercise Testing During Cardiac Catheterization in Mitral Stenosis

HEIKKI V. HUIKURI, MD, and JUHA T. TAKKUNEN, MD

To examine the value of preoperative isometric exercise testing during cardiac catheterization in patients with mitral stenosis, the isometric handgrip exercise test was performed on 28 patients during preoperative diagnostic catheterization. Eighteen patients who subsequently underwent mitral valve surgery were recatheterized and reevaluated clinically 12 months after operation. Preoperatively, the patients were divided into 2 groups: 16 whose mean mitral valve pressure gradient increased >4 mm Hg during isometric exercise (group A) and 12 whose pressure gradient decreased or increased <4 mm Hg (group B). The ejection fraction remained unchanged and the peak systolic pressure/end-systolic volume ratio increased during isometric exercise in group A ($p < 0.001$). In group B, the ejection fraction decreased ($p < 0.001$) and the peak systolic pressure/end-systolic volume ratio remained unchanged. In the total group, a positive correlation existed between the change in mean mitral valve pressure gradient during isometric exercise and the changes in measures of left ventricular function during exercise. The patients in group A had a significant improvement in both symptoms and in exercise tolerance as determined by symptom-limited bicycle ergometry after surgery. The patients in group B showed minimal or no symptomatic improvement and their exercise tolerance did not improve. The change in mitral valve pressure gradient during isometric exercise appears to reflect the left ventricular response to exercise.

(Am J Cardiol 1983;52:540–543)

Isometric exercise reveals left ventricular (LV) dysfunction and increases the mitral valve pressure gradient in some patients with mitral stenosis (MS).[1,2] The isometric handgrip exercise test can be performed easily and safely during cardiac catheterization without causing major disturbances in the pressure recordings.[3,4] The present study evaluates whether the measurement of mitral valve pressure gradient during isometric handgrip exercise would give useful information for therapeutic decisions regarding patients with MS.

Patients and Methods

Patients: A consecutive series of 28 patients with clinically and echocardiographically suspected significant MS underwent cardiac catheterization and a concurrent handgrip test. Patients with more than trivial mitral regurgitation (regurgitant fraction >0.20) or aortic valve disease (>10 mm Hg peak systolic pressure gradient across the aortic valve or clinical signs of aortic regurgitation) were excluded. Ten patients underwent open mitral commissurotomy and 8 patients mitral valve replacement. The patients underwent recatheterization and were reevaluated clinically 12 months after surgery.

The patients were divided preoperatively into 2 groups according to the change in the mean mitral valve pressure gradient during isometric exercise. Sixteen patients whose valvular gradient increased >4 mm Hg during isometric exercise formed group A and 12 patients whose pressure gradient increased <4 mm Hg or decreased formed group B. The mean age of the patients in group A, which included 9 females and 4 males, was 49 ± 13 years, and that of group B, which included 8 females and 4 males, was 51 ± 9 years. Nine patients in group A and 5 in group B had atrial fibrillation; the others were in sinus rhythm. None of the patient had any conversion of atrial fibrillation to sinus rhythm or vice versa after surgery. Most of the patients were receiving digitalis therapy during the pre- and postoperative studies. None were receiving beta-blocking or vasodilating agents. Functional impairment was determined by the New York Heart Association classification of the grade of symptoms and by the symptom-limited bicycle exercise test both pre- and postoperatively. The bicycle exercise test was performed using a Godard-Statham electrically braked bicycle ergometer. The work load was increased progressively (15 W/min in men and 10W/min in women) until symptoms of dyspnea or exhaustion. The maximal work load achieved was then used for analysis of data. All the patients gave informed consent to the exercise tests and catheterization studies.

Invasive studies: Pre- and postoperative right and left-sided cardiac catheterizations were performed through the cubital vein and the brachial artery approach. Right atrial pressures, pulmonary pressures and pulmonary capillary wedge pressures were recorded with a Statham P23Ia transducer. Left ventricular (LV) pressures were recorded with a Statham P23Ia transducer or, whenever possible, with a high-fidelity Millar tip transducer, with pressures matched against fluid-filled luminal pressures. A data acquisition system (Hewlett-Packard 5600B) was used for the standard recording of pressures. Selective biplane LV cineangiography

	<0.001		NS		<0.001		<NS		<0.005	

Values are mean ± SD; p values with paired *t* test between data at rest and during exercise.
EDVI = end-diastolic volume index; ESVI = end-systolic volume index; EF = ejection fraction; PSP/ESVI = ratio between peak systolic ventricular pressure and end-systolic volume index; SV = stroke volume.

was performed in the 45° right anterior oblique position. Coronary angiography was performed on 6 patients with symptoms of angina pectoris (5 in group B and 1 in group A) using the Judkins technique. No coronary artery bypass grafts were performed during surgery.

Isometric exercise tests: After pre- and postoperative ventriculography, LV pressures were recorded until they returned to baseline levels. Then, at least 20 minutes after resting cineangiography, the patients were asked to perform a handgrip test as described previously.[5] LV pressures, mean mitral valve pressure gradient and heart rate were determined every minute for 4 minutes during sustained handgrip. After 4 minutes, and with the patients still performing the grip, LV cineangiography was again carried out.

Measurements: LV volumes were measured from 1 or 2 representative beats and the postextrasystolic beats were discarded. In the patients with atrial fibrillation, the volume measurements were taken on the beats that most closely approximated the average RR interval for the basal ventricular response. In the postoperative angiograms, the cycle length chosen for analysis was that which most resembled that of the preoperative cycle. The contours of the left ventricle were digitized at biplane with a sonic pen on the projection screen using HP 5600B system and biplane area-length method for volumes.[6] The LV pressure curve was recorded simultaneously with the angiogram, or just before it when fluid-filled catheters were used, at a paper speed of 150 mm/s and was digitized and synchronized with the corresponding volume data with the aid of the HP 5600B system. The mean mitral valve pressure gradient and the diastolic filling period were measured both at rest and during isometric exercise by simultaneously recording pulmonary capillary wedge and LV pressures. The mitral valve area was then calculated from the modified Gorlin formula[7] using both the angiographically determined and the Fick method–determined total LV stroke volume to represent the flow of the orifice. The mitral regurgitant fraction was measured by subtracting the stroke volume, determined by the Fick method, from the total LV stroke volume.

Calculations: Statistical analysis was performed by using the paired *t* test to compare the individual data at rest with those obtained during isometric exercise and the preoperative data with the postoperative data. The Student *t* test was used to compare changes between the 2 groups. Linear regression analysis was used to calculate correlations.

Results

Pre- and postoperative hemodynamic data: A summary of preoperative hemodynamic data at rest and during isometric exercise is presented in Table I. Preoperatively, heart rate and LV peak systolic pressure increased significantly and equally in both groups during exercise. LV end-diastolic pressure remained unchanged in group A, but increased significantly in group B. LV end-diastolic pressure increased >2 mm Hg in all but 2 patients in group B during exercise. The mitral valve area did not change significantly during exercise in either group. The diastolic filling period decreased significantly and equally in both groups during exercise ($p < 0.001$).

Postoperatively, the changes in heart rate and LV peak systolic pressure were equal to preoperative changes during exercise in both groups. The LV end-diastolic pressure did not change in group A and increased from 12 ± 5 to 17 ± 4 mm Hg ($p < 0.02$) in group B during exercise after surgery. The mean mitral valve pressure gradient at rest decreased significantly after surgery in both groups ($p < 0.001$). None of the patients had significant residual stenosis or restenosis after surgery.

Pre- and postoperative angiographic data: A summary of the preoperative angiographic data is presented in Table II. The end-diastolic volume index did not change in either group during exercise; the end-systolic volume index increased significantly in group B and did not change in group A. The ejection fraction and stroke volume did not change in group A and decreased significantly in group B, while the peak systolic

pressure/end-systolic volume index ratio increased in group A and did not change in group B during exercise. Three of 6 patients with angina pectoris (all in group B) had significant coronary stenosis in one or more coronary vessels on coronary angiography. None of these patients underwent mitral valve surgery.

None of the resting angiographic values changed significantly after surgery in either group. The changes in LV volumes and ejection fraction during exercise postoperatively were equal to those during preoperative exercise testing in both groups.

Correlation of the change in mitral valve pressure gradient during exercise with other hemodynamic and angiographic data: The change in mitral pressure gradient during exercise did not correlate with any of the resting hemodynamic or angiographic data or with the changes in heart rate, LV peak systolic pressure, diastolic filling period or LV end-diastolic volume during exercise. A correlation did exist between the change in mitral pressure gradient during exercise and changes in ejection fraction ($r = 0.78$, $p < 0.001$) (Fig. 1), end-systolic volume index ($r = 0.69$, $p < 0.001$), peak systolic pressure/end-systolic volume ratio ($r = 0.61$, $p < 0.001$) and LV end-diastolic pressure ($r = 0.73$, $p < 0.001$).

Pre- and postoperative clinical data: The individual pre- and postoperative functional class of the patients is presented in Figure 2. All patients in group A showed symptomatic improvement after operation. In group B, 2 patients remained in class III and 3 were in class II postoperatively. Figure 3 presents the change in the maximal work load tolerated in bicycle ergometry. The maximal work load increased from 66 ± 20 to 94 ± 28 W ($p < 0.001$) in group A and did not change in group B (58 ± 26 W preoperatively and 55 ± 5 W postoperatively, difference not significant) after surgery.

Discussion

Response to isometric exercise in mitral stenosis: Isometric exercise has been used to evaluate LV functional reserve in various cardiovascular disorders.[1–4] Isometric exercise induces a relatively modest increase in heart rate compared with dynamic exercise,[8] and therefore may offer a better means of evaluating the LV response to exercise in MS without excessive complications from a rate-related increase in inhibition of LV filling. The normal response to isometric exercise is a maintenance of ejection fraction and an increase of peak systolic pressure/end-systolic volume ratio.[9,10] More than a half of our patients showed a similiar response to handgrip exercise, indicating a normal response to stress. In 12 patients the ejection fraction decreased during exercise, suggesting impaired myocardial contractile reserves. The change in mitral valve pressure gradient during exercise correlated well with the changes in ventricular function. The increase of LV end-diastolic pressure reflected also the reduced re-

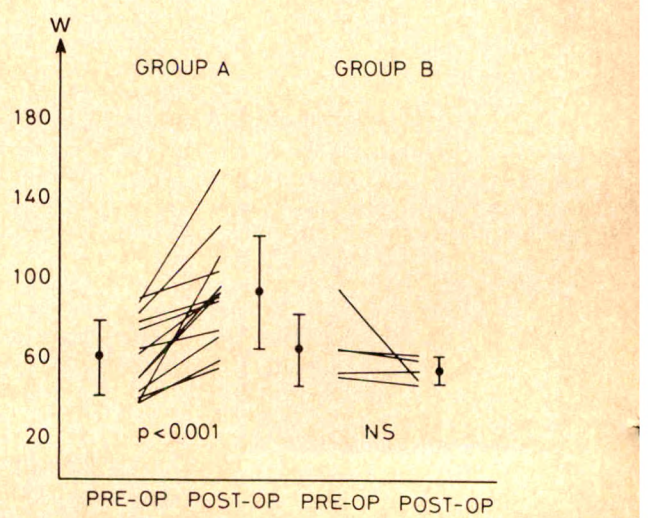

FIGURE 3. Individual values in the maximal work load tolerated in bicycle ergometry before and after mitral valve surgery in groups A and B.

sponse to exercise. However, in 2 patients the LV end-diastolic pressure did not increase despite the decrease in ejection fraction.

The increase in LV diastolic pressure without a significant increase in left atrial pressure may explain why the pressure gradient did not increase in some patients. Previously, the deterioration in LV ejection fraction in response to isometric exercise has been shown to be related to LV asynergy and stiffness.[9] Horwitz et al[11] demonstrated that patients with MS whose LV response to isometric exercise is reduced show posterobasal wall motion abnormalities in cineangiography. Contraction abnormalities, generally in the posterobasal area, also correlate well with abnormal LV response to afterload stress induced by angiotensin in MS.[12] Ischemic wall motion abnormalities due to coronary artery disease might well explain the reduced response to exercise. Two patients in group B had normal coronary arteriography and half of the patients in group B had no symptoms of angina pectoris; therefore, rigidity of posterobasal area of the left ventricle may explain the reduced LV response to isometric exercise.

Value of isometric exercise testing in predicting the postoperative outcome: LV dysfunction is a commonly suspected cause of poor surgical results in patients treated by either commissurotomy or valve replacement.[13–15] Our data are consistent with these findings; that is, the patients whose LV response to exercise was impaired preoperatively continued to have a reduced LV response to stress after surgery and their functional improvement was minimal. According to these findings, the mechanical obstruction imposed by the diseased mitral valve may not be the sole basis for the diminished exercise tolerance. Some of the symptoms experienced by the patients with MS may also be the result of impaired LV function. In such cases, surgical dilatation of the mitral valve cannot bring about the expected functional improvement.

The indications for surgery in MS are generally based on the symptomatic severity and degree of valvular lesion. Selzer[16] reported many patients with MS for whom careful clinical evaluation appeared to justify placement in functional class III, but whose cardiac catheterization revealed only trivial mitral valve obstruction. Although commissurotomy is a safe procedure, valve replacement still carries some risk of mortality and the valve prosthesis in the mitral position presents a modest risk of postoperative complications. To avoid unnecessary surgical interventions, more objective data may thus be needed when evaluating the indications for surgery, especially when a discrepancy exists between functional impairment and the degree of valvular obstruction. If cardiac catheterization is needed because of this discrepancy or for other reasons,[17] measurement of the mitral valve pressure gradient during isometric handgrip exercise, which can be performed quite safely and easily in our experience, might give some valuable information to assist in such therapeutic decisions.

Possible methodologic limitations: The variations in cycle length that occur with atrial fibrillation may affect the mitral valve pressure gradient. The diastolic filling period did not differ significantly between the groups either at rest or during exercise; therefore, the cycle length variation was probably not of major significance in the responses in the valvular pressure gradients during exercise in groups A and B. Also, coronary angiography was not performed in patients without angina pectoris. Significant coronary artery disease that is not clinically suspected has not been shown to be common in patients with MS.[18]

Influence of Verapamil Therapy on Left Ventricular Performance at Rest and During Exercise in Hypertrophic Cardiomyopathy

PETER HANRATH, MD, MICHAEL SCHLÜTER, PhD, FRANK SONNTAG, MD, JÖRG DIEMERT, MD, and WALTER BLEIFELD, MD

To determine the hemodynamic effect of verapamil at rest and during exercise, 18 patients with hypertrophic cardiomyopathy were studied before and after 7 weeks of treatment with oral verapamil (maximal dose, 720 mg/day). At rest and at peak exercise, verapamil produced a significant increase in left ventricular (LV) systolic performance in terms of stroke volume index (rest, from 43 ± 11 to 53 ± 11 ml/m^2, p <0.001; exercise, from 46 ± 11 to 51 ± 10 ml/m^2, p <0.01), whereas heart rate decreased (rest, from 81 ± 14 to 70 ± 11 min^{-1}, p <0.001; exercise, from 150 ± 21 to 141 ± 18 min^{-1}, p <0.01). Cardiac index at rest and during exercise remained unchanged. Systolic vascular resistance did not change at rest, but decreased significantly during exercise (974 ± 243 to 874 ± 174 dynes s cm^{-5}; p <0.05). After verapamil administration, pulmonary artery pressures did not change at rest, but decreased significantly during exercise. This was probably due to a shift in the LV pressure-volume relation. The improvement in LV hemodynamics was associated with a significant increase in exercise capacity. The findings of this study indicate that in patients with hypertrophic cardiomyopathy, hemodynamic improvement at rest and during exercise can be achieved by chronic administration of verapamil.

(Am J Cardiol 1983;52:544–548)

Recently, several investigators have described the effectiveness of the slow calcium channel-blocking agent verapamil in the treatment of hypertrophic cardiomyopathy, although the exact mode of action of the drug in this specific disease is still unclear.[1–8] These studies report a beneficial effect of verapamil on symptoms, exercise capacity and left ventricular (LV) hemodynamics. Acute or chronic administration of verapamil results in a reduction of the LV pressure gradient and in an improvement of LV diastolic performance at rest.[5,7,8–12] However, no data are available on the hemodynamic effect of this drug on LV function during exercise. This study evaluates the effect of chronic high-dose verapamil administration on LV performance at rest and during exercise in patients with hypertrophic cardiomyopathy.

Methods

Patients: Eighteen patients, 4 men and 4 women, aged 25 to 58 years (mean 45 ± 10), participated in the study. In all patients the diagnosis of hypertrophic cardiomyopathy was based on clinical examination, echocardiographic study and on right- and left-sided cardiac catheterization. The echocardiographic criterion for hypertrophic cardiomyopathy was a disproportionate thickening of the ventricular septum with respect to the LV free wall (septal–LV free wall thickness ratio ≥1.5) in the absence of other acquired or congenital heart diseases. Coronary artery disease was excluded by selective coronary angiography. Six patients (5 men and 1 woman) had nonobstructive hypertrophic cardiomyopathy and 12 (9 men and 3 women) had an obstructive form with an LV pressure gradient either at rest or after provocation (postextrasystolic or amyl nitrite–induced gradient ≥30 mm Hg). The mean resting gradient was 53 ± 21 mm Hg (range 30 to 90) and the mean gradient at provocation was 95 ± 49 mm Hg (range 30 to 175) (Table I). All patients except 1 with atrial fibrillation (Case 16) had sinus rhythm. Three patients had angiographically proved mitral regurgitation. In 2 of the 3 (Cases 7 and 8), it was mild (Class I); in the third (Case 16), it was severe (Class III).

LV exercise hemodynamics were measured with a Swan-Ganz thermodilution catheter advanced to the pulmonary artery. Cardiac output was measured in triplicate by thermodilution. Pulmonary artery pressure measurements were based on the analysis of 5 consecutive cycles.

Arterial blood pressure was measured with cuff manometer. Exercise was performed on a braked bicycle ergometer with the patient in the supine position. Initial work load was 50 W; it increased progressively by 25 W at 3-minute intervals, while patients maintained a constant pedaling rate of 40 rpm.

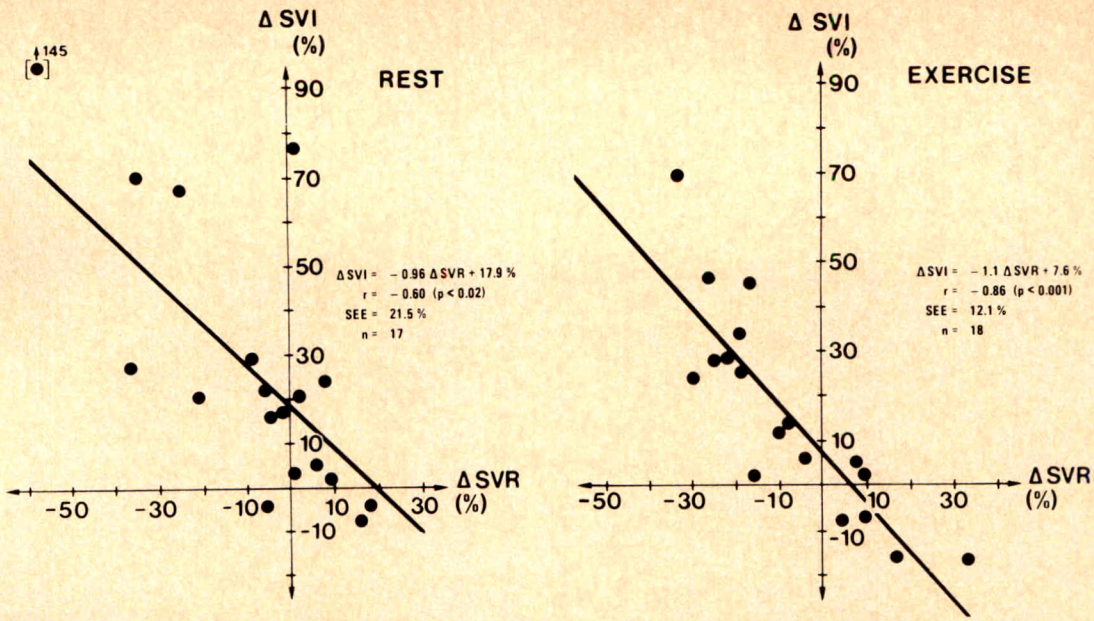

FIGURE 1. Correlation between percent change in systemic vascular resistance (ΔSVR) and percent change in stroke volume index (ΔSVI) at rest (**left panel**) and at peak exercise (**right panel**) after verapamil treatment. The **black circle in brackets** in the **left panel** was excluded from the regression calculations. SEE = standard error of the estimate.

Maximal work rate in the individual patient was calculated by summing the work rate in kpm/min (W) of each exercise step achieved.[13]

Hemodynamic measurements were taken at rest and at maximal exercise. Exercise was performed until angina, limiting fatigue or dyspnea developed. In patients who had angina, exercise was continued until angina caused them to stop. In 1 patient (Case 6), exercise was discontinued because of severe arrhythmia (Lown grade 4B). In Cases 6 and 8, control pulmonary artery pressures could not be determined at rest or during exercise for technical reasons.

All medication was stopped at least 3 days before the hemodynamic control measurement was performed. Thereafter, each patient received 40 mg of verapamil 3 times/day. Within the next 6 weeks the dosage was slowly increased in 17 patients to a maximal dosage of 120 mg 6 times/day. One patient (Case 15) received a maximum of 120 mg 4 times/day. After an average treatment of 7 weeks (range 4 to 12) with maximal verapamil dosage, repeat hemodynamic measurements at rest and during maximal exercise were performed in each patient. The examination was performed 2 hours after the morning dose. No serious adverse effects relating to the large verapamil dosage[14] and complications related to the investigations were observed.

Calculations and statistical analysis: Cardiac index (CI, liters/min/m^2) was calculated as cardiac output (CO)/body surface area. Stroke volume index (ml/m^2) was calculated as CI/heart rate. Pulmonary vascular resistance (dynes s cm^{-5}) was calculated as (MPAP − EDPAP)/CO × 80, where MPAP = mean pulmonary artery pressure and EDPAP = end-diastolic pulmonary artery pressure. Systemic vascular resistance (dynes s cm^{-5}) was calculated as ($\overline{AP}$/CO) × 80, where $\overline{AP}$ = mean arterial pressure. (Mean arterial pressure was estimated from the formula AP = SP + 2 DP/3, where SP = peak systolic and DP = diastolic blood pressure.[15] In the patient with atrial fibrillation, the mean AP was determined from several consecutive readings.)

Results are expressed as mean values ±1 standard deviation. A Student *t* test for paired comparison was used to compare values before and after treatment. Differences were regarded as significant at $p < 0.05$.

Results

Individual and mean values of the hemodynamic measurements at rest and at peak exercise before and after chronic verapamil therapy are listed in Table I. On an average, the maximal work rate improved significantly from initially 626 ± 296 to 779 ± 363 W after verapamil therapy ($p < 0.01$). Compared with control measurements, the stroke volume index increased significantly at rest and during exercise (rest, from 43 ± 11 to 53 ± 11 ml/m^2, $p < 0.001$; exercise, from 46 ± 11 to 51 ± 10 ml/m^2, $p < 0.01$), whereas resting and exercise heart rate decreased from 81 ± 14 min^{-1} to 70 ± 11 min^{-1} ($p < 0.001$) and from 150 ± 21 min^{-1} to 141 ± 18 min^{-1} ($p < 0.01$), respectively. Consequently, cardiac index did not change (rest, from 3.5 ± 0.7 to 3.7 ± 0.9 liters/min/m^2, difference not significant [NS]; exercise, from 6.7 ± 1.4 to 7.2 ± 1.2 liters/min/m^2, NS).

The mean arterial blood pressure decreased significantly (rest, from 107 ± 9 to 102 ± 10 mm Hg, $p < 0.05$; exercise, from 145 ± 15 to 140 ± 16 mm Hg, $p < 0.05$), as did systemic vascular resistance during exercise (974 ± 243 to 874 ± 174 dynes s cm^{-5}, $p < 0.05$). Significant negative correlations were found at rest and at maximal exercise between the percent changes in systemic vascular resistance and stroke volume index (Fig. 1). Pulmonary vascular resistance remained unchanged.

Pulmonary artery pressures, on an average, did not change at rest. During exercise, a significant decrease in pulmonary artery pressures was observed. Systolic pulmonary artery pressure at maximal exercise decreased from 61 ± 18 mm Hg before to 51 ± 13 mm Hg after verapamil therapy ($p < 0.01$), while mean and end-diastolic pulmonary artery pressures decreased from 43 ± 15 to 37 ± 10 mm Hg ($p < 0.02$) and from 32 ± 11 to 24 ± 7 mm Hg ($p < 0.001$), respectively.

A general decrease in pulmonary artery pressures during exercise was observed in 12 patients. In 2 more

(Cases 5 and 18), only end-diastolic pressure decreased, whereas systolic and mean pulmonary artery pressures either increased or the former remained constant and the latter increased. One patient (Case 14) had no change in end-diastolic pulmonary artery pressure (but had increased systolic and mean pressures); another patient (Case 17) had increased end-diastolic pulmonary artery pressure (with no change in systolic and mean pressures). However, the decrease in end-diastolic pulmonary artery pressure observed at maximal exercise in these 14 patients was associated with an improvement in stroke volume index of at least 5% in only 8 patients; no change occurred in 2 (Cases 10 and 12) and a deterioration in stroke volume index was seen in 4 (Cases 2, 3, 7 and 18). Stroke volume also improved in the 2 patients in whom no control measurements were available (Cases 6 and 8) and in the 2 with unchanged or increased end-diastolic pulmonary artery pressure (Cases 14 and 17).

Figure 2 illustrates the general relation between end-diastolic pulmonary artery pressure and stroke volume index in our study group. The mean values (±SD) are shown for each measurement at rest and at maximal exercise for the control and the verapa state. At rest, chronic verapamil treatment does change end-diastolic pulmonary artery pressure, w stroke volume is significantly increased. During exerc stroke volume index does not change significantly eit before or after verapamil treatment. At maximal ex cise, however, end-diastolic pulmonary artery press is significantly reduced after administration of ve pamil and stroke volume index is still significantly creased. Thus, on an average, there is an upward a leftward shift of the patient's hemodynamic exerc status after verapamil therapy, indicating impro cardiac performance.

In the small group of patients studied, there was obvious difference in the hemodynamic behavior at r and with exercise between the obstructive and nonobstructive form of hypertrophic cardiomy athy.

Discussion

The present data show that chronic verapamil th apy in patients with hypertrophic cardiomyopathy l a beneficial effect on LV hemodynamics at rest a

= pulmonary vascular resistance; R = rest; SD = standard deviation; SPAP = systolic pulmonary artery pressure; SVI = stroke volume index; SVR = systemic vascular resistance; V = verapamil; ∅ = not available.

during exercise. LV systolic performance in terms of stroke volume index improved, on an average, by 23% at rest and by 12% at maximal exercise.

We believe that the main pharmacologic effects of chronic high-dose verapamil application responsible for the increase in stroke volume are the vasodilating action and the decrease in heart rate. Verapamil has been shown to have a systemic vasodilative effect[16,17] in patients with various types of heart disease. This finding is reflected in our study by the decreased mean arterial pressures. A significant reduction of systemic vascular resistance could only be documented during exercise, yet the significant negative correlations between the percent changes in systemic vascular resistance and stroke volume index at rest as well as during exercise (Fig. 1) strongly suggest that one of the causes for the improvement in systolic performance in our study group is the vasodilating effect of verapamil. A similar increase in stroke volume accompanied by a moderate decline in systemic resistance was also reported by Chatterjee et al.[11]

The heart rate at rest and during exercise was significantly reduced in our patient group. The reduction of heart rate in patients with hypertrophic cardiomyopathy who received verapamil therapy has been observed by other investigators[5,8,18] and probably reflects the depressing action of the drug on the sinus node automaticity when administered chronically. The reduced heart rate causes improved diastolic filling, which in turn improves stroke volume according to the Frank-Starling mechanism. As a consequence of decreased heart rate and increased stroke volume index, cardiac index remained constant.

Although cardiac output did not increase, most patients performed more exercise after verapamil therapy, as previously reported by Rosing et al.[5] Several factors may be considered responsible for the improved exercise capacity. The significant decrease in pulmonary artery pressures during exercise may have improved working capacity because of an amelioration of dyspnea. In addition, the decrease in end-diastolic pulmonary artery pressure—representing a decrease in LV end-diastolic pressure—may indicate reduced subendocardial ischemia during exercise secondary to decreased LV diastolic wall tension. Furthermore, heart rate, as one of the major determinants of myocardial oxygen con-

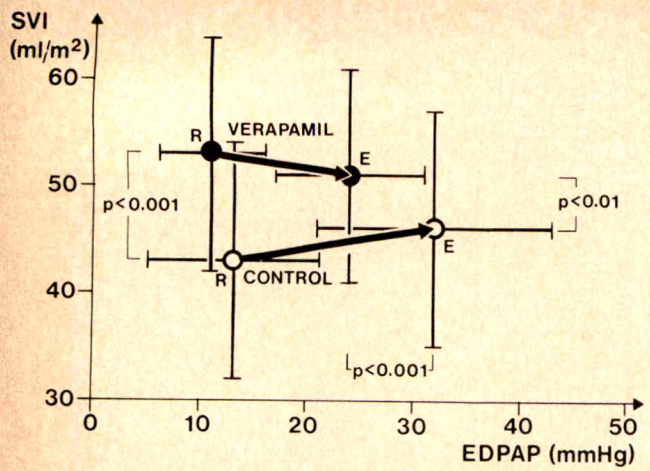

FIGURE 2. Mean values (±1 standard deviation) of end-diastolic pulmonary artery pressure (EDPAP) and stroke volume index (SVI) at rest (R) and at maximal exercise (E) in the same group of patients before (CONTROL) and after (VERAPAMIL) chronic treatment with verapamil. Verapamil significantly ($p < 0.001$) increased SVI at rest, while EDPAP remained constant. At exercise, in the verapamil group, SVI remained significantly increased ($p < 0.01$) with respect to the control group and EDPAP significantly decreased ($p < 0.001$). This reflects improved cardiac performance at rest and during exercise after verapamil. The p values were determined from paired *t* tests.

sumption, was significantly reduced during exercise after verapamil administration. In patients with obstructive hypertrophic cardiomyopathy, oral verapamil also diminished the pressure gradient,[3] further reducing myocardial oxygen demand.

Verapamil has been reported to have no venous pooling effect.[16,17] Although the present data do not explicitly exclude venous pooling (since right atrial pressures were not measured), the constant resting end-diastolic pulmonary artery pressure before and after verapamil administration suggests no change in the circulating blood volume. Other authors have made similar observations.[4,10,11] They also found that resting LV end-diastolic pressure remained unchanged after acute or chronic verapamil administration.

The mechanism underlying the reduction of pulmonary artery pressure during exercise after verapamil treatment is unclear. In patients with hypertrophic cardiomyopathy, several groups of investigators reported that verapamil causes an improvement in LV relaxation, as reflected in shortened isovolumic relaxation time, increased rate of LV filling or wall thinning, reduced LV end-diastolic pressure and a downward shift of the LV pressure-volume curve.[7,8,10–12] These alterations in diastolic function may be caused by myocardial ischemia. Despite normal extramural coronary arteries, stressed-induced ischemia has been documented in patients with hypertrophic cardiomyopathy by electrocardiographic stress testing, thallium scintigraphy and myocardial lactate sampling.[19] In these patients, ischemia was believed to be caused by narrowed intramural vessels[20] or by an imbalance in the oxygen supply-demand ratio.

The results of this study demonstrate that chronic oral verapamil administration can improve LV hemodynamics at rest and during exercise in many patients with hypertrophic cardiomyopathy. The mild adverse hemodynamic effects during verapamil therapy in individual patients were not accompanied by corresponding symptoms or clinical findings and in no case led to a withdrawal of verapamil.

Introducing an indispensable guide to pacemakers and pacemaker selection!

Concise and clinically oriented, this timely monograph presents the state-of-the-art in cardiac pacing, lead selection and pacemaker selection. You'll find detailed coverage of antitachycardia units, defibrillation units, and telemetry, as well as clear discussion of dual- and single-chamber pacing. Drugs and their interaction with pacemaker therapy, and the special considerations affecting cardiac pacing in children, are carefully specified. Lavish illustration of the radiology of cardiac pacemakers is also of interest. Special emphasis is given to providing the most up-to-date information on the newest pacemaker models, recently developed pacing techniques, and the revolutionary advances in multiprogrammable pacemakers.

PACEMAKER THERAPY will prove an invaluable guide to both pacemaker and patient selection.

Contents: Hemodynamic Effects of Cardiac Pacing · Indications for Pacemaker Therapy Based on Electrophysiologic Testing · Pacemaker Implantation: Surgical Techniques · Available Types of Pacemakers · The Radiology of Cardiac Pacemakers · Electrocardiographic Analysis of Normal and Abnormal Pacemaker Function · Programmable Pacemakers: Technical Features and Clinical Applications · Atrial Demand and AV Sequential Pacemakers · Pacemaker Management of Cardiac Arrhythmias · Drugs and Pacemaker Therapy · Experience with Permanent Pacing in the Sick Sinus Syndrome · Automatic Implantable Defibrillator · Cardiac Pacing in Children · Use of Dual-Demand AV Sequential (DVI, MN) Pacemakers in the Management of Supraventricular Tachycardias · Pacemaker Technology: Energy Sources · Pacemaker Technology: Pacing Leads · Future Generation Pacemakers.

A GUIDE TO CARDIAC PACEMAKERS

This unique book is the only comprehensive Atlas of lithium pacemakers now available. Photographs, radiographs, and technical specifications are provided for each pacemaker. A Lead Atlas gives descriptions and photographs of available leads.

NITRODISC™
(NITROGLYCERIN)
5 mg/24 hr
10 mg/24 hr discs

DESCRIPTION: Nitrodisc incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths which release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: Nitrodisc should be applied once each day. To use Nitrodisc, follow the instructions on the package. Nitrodisc should be applied to an intact skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new Nitrodisc should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller Nitrodisc, and that the larger Nitrodisc be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

Contraindications for nitroglycerin include increased intraocular pressure. Side effects include headache, hypotension, flushing, and dizziness. In terminating treatment, both the dosage and frequency of application must be gradually

Please see the preceding page for a brief summary of the complete prescribing

Most older patients have difficulty "getting along with their hypnotics.

RESTORIL® (temazepam) does "get along" very well with older patients because:

Early morning awakening, a frequent problem, is significantly reduced with RESTORIL therapy. Patients get a restful night's sleep and awaken alert the next morning. There are very few residual effects and drug accumulation is insignificant.*

Unlike flurazepam (Dalmane® CIV), age is generally not an important determinant of the pharmacokinetics of RESTORIL.[1,2]

Unlike flurazepam, RESTORIL (temazepam) can be given concomitantly with cimetidine without changing total clearance time.[1]

RESTORIL, because of its simple metabolic pathway, is not contraindicated in patients with impaired liver or kidney function and should present fewer problems.[1,2]

*Recommended initial dose for elderly and/or debilitated patients is one 15-mg capsule.

1. Data on file, Medical Department, Sandoz Pharmaceuticals.
2. Lader MH: J Clin Psychiatry *44*:47, 1983.

RESTORIL® (temazepam) "gets along" very well with most older patients.

RESTORIL® C IV
15 mg
30 mg
capsules

(temazepam)

compatible with your older patients' metabolism and medication

Please see brief summary of prescribing information on next page.

Compatible with your older patients' metabolism and medication

R TORIL®

(IV) 15 mg 30 mg capsules

(temazepam)

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

Laboratory Tests: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

Pregnancy: Pregnancy Category X. See Contraindications.

Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.

ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). *Sizes and strengths available to Armed Services:* Restoril (temazepam) capsules, in bottles of 500: 15 mg capsules NSN/6505-01-116-0481; 30 mg capsules NSN/6505-01-116-0482.

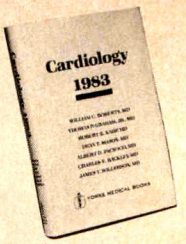
Cardiology 1983

The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery



What is Cardiology 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, **written**, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

Update your echo lab with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leakage. Monitors valve function over time.
- Color spectral patterns locate and grade shunts.
- Displays ECG trace for time reference. Phono trace for correlation of heart sounds with Doppler flow velocity patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Call 1-800-334-4531 to place your order, for in-depth information or an on-site demonstration.

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PROMOTES CORONARY BLOOD FLOW TO REDUCE MYOCARDIAL ISCHEMIA

Angina is caused by ischemia that results from atherosclerosis alone, vasoconstriction alone, or a combination of both. By preventing vasoconstriction, and increasing myocardial blood supply, Procardia may help limit angina* due to an inadequate supply of blood.

*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina), Procardia has been effective in controlled trials of up to eight weeks' duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete. In general, dilation of coronary arteries does not appear to be an important part of Procardia action in classical angina.

for the varied faces of angina.

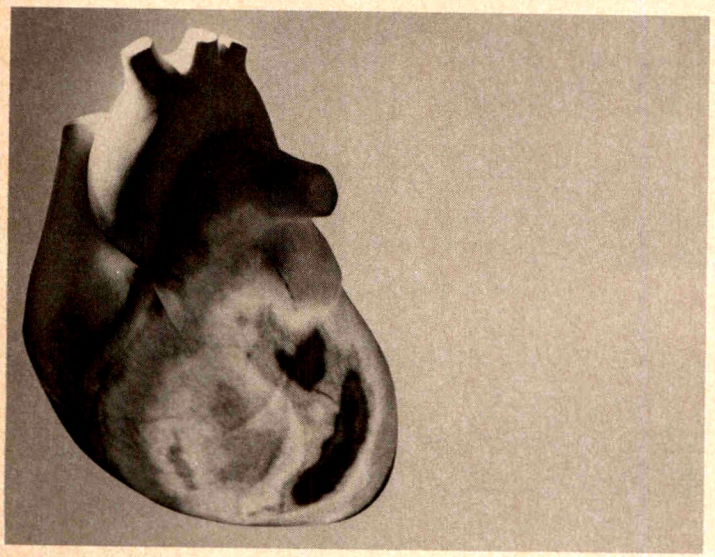
PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Please see PROCARDIA® *brief summary on next page.*

increasing myocardial blood flow



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

BRIEF SUMMARY
PROCARDIA* (nifedipine) **CAPSULES** F
INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is in
the management of vasospastic angina confirmed by any of the following criteria: 1
pattern of angina at rest accompanied by ST segment elevation, 2) angina or coror
spasm provoked by ergonovine, or 3) angiographically demonstrated coronary arte
In those patients who have had angiography, the presence of significant fixed obstr
ease is not incompatible with the diagnosis of vasospastic angina, provided that the
teria are satisfied. PROCARDIA may also be used where the clinical presentation
possible vasospastic component but where vasospasm has not been confirmed, e
pain has a variable threshold on exertion or in unstable angina where electrocardiogr
ings are compatible with intermittent vasospasm, or when angina is refractory to ni
or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA i
for the management of chronic stable angina (effort-associated angina) without e
vasospasm in patients who remain symptomatic despite adequate doses of beta blo
or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effect
trolled trials of up to eight weeks duration in reducing angina frequency and increasir
tolerance, but confirmation of sustained effectiveness and evaluation of long-terr
these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PF
and beta-blocking agents may be beneficial in patients with chronic stable angina, bu
information is not sufficient to predict with confidence the effects of concurrent trea
pecially in patients with compromised left ventricular function or cardiac conduction
ities. When introducing such concomitant therapy, care must be taken to mon
pressure closely since severe hypotension can occur from the combined effects of
(See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensiv
PROCARDIA is modest and well tolerated, occasional patients have had excessive
tolerated hypotension. These responses have usually occurred during initial titratio
time of subsequent upward dosage adjustment, and may be more likely in patients or
itant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been repor
tients receiving PROCARDIA together with a beta blocking agent who underwent co
tery bypass surgery using high dose fentanyl anesthesia. The interaction with
fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, bu
sibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in othe
procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA t
tients where surgery using high dose fentanyl anesthesia is contemplated, the physici
be aware of these potential problems and, if the patient's condition permits, sufficie
least 36 hours) should be allowed for PROCARDIA to be washed out of the boc
surgery.

Increased Angina: Occasional patients have developed well-documented incre
quency, duration or severity of angina on starting PROCARDIA or at the time of d
creases. The mechanism of this response is not established but could result from
coronary perfusion associated with decreased diastolic pressure with increased hea
from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may
withdrawal syndrome with increased angina, probably related to increased sensitivit
cholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and
expected to exacerbate it by provoking reflex catecholamine release. There have be
sional reports of increased angina in a setting of beta blocker withdrawal and PROCA
tiation. It is important to taper beta blockers if possible, rather than stoppi
abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have d
heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be
risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral
resistance, careful monitoring of blood pressure during the initial administration
tion of PROCARDIA is suggested. Close observation is especially recommended for
already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with ar
sodilation and not due to left ventricular dysfunction, occurs in about one in ten patient
with PROCARDIA. This edema occurs primarily in the lower extremities and usually
to diuretic therapy. With patients whose angina is complicated by congestive heart fai
should be taken to differentiate this peripheral edema from the effects of increasing le
ular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warning
rience in over 1400 patients in a non-comparative clinical trial has shown that con
administration of PROCARDIA and beta-blocking agents is usually well tolerated.
have been occasional literature reports suggesting that the combination may increase
lihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates,
have been no controlled studies to evaluate the antianginal effectiveness of this comb

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels i
twelve normal volunteers. The average increase was 45%. Another investigator fou
crease in digoxin levels in thirteen patients with coronary artery disease. In an unc
study of over two hundred patients with congestive heart failure during which digoxin b
els were not measured, digitalis toxicity was not observed. Since there have been iso
ports of patients with elevated digoxin levels, it is recommended that digoxin l
monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible
under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to ma
fedipine caused reduced fertility at a dose approximately 30 times the maximum recom
human dose.

Pregnancy: Category C. Please see full prescribing information with reference to terato
in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-
ness, peripheral edema, nausea, weakness, headache and flushing each occurring
10% of patients, transient hypotension in about 5%, palpitation in about 2% and sy
about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA
comitant antianginal medication. Additionally, the following have been reported:
cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation,
mation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in
dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rare
duction of PROCARDIA therapy was associated with an increase in anginal pain, poss
to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable
natural history of the disease in these patients. It remains possible, however, that
many of these events were drug related. Myocardial infarction occurred in about 4% of
and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias
duction disturbances each occurred in fewer than 0.5% of patients.

Laboratory Tests: Rare, mild to moderate, transient elevations of enzymes such as
phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident o
cantly elevated transaminases and alkaline phosphatase was seen in a patient with a h
gall bladder disease after about eleven months of nifedipine therapy. The relation
PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been as
with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been
twice in the extensive world literature.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg o
pine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 3
0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should
tected from light and moisture and stored at controlled room temperature 59° to 77°F
25°C) in the manufacturer's original container.

More detailed professional information available on request.

Changing Results and Concepts in the Surgical Treatment of Double-Outlet Right Ventricle: Analysis of 137 Operations in 126 Patients

GIAN PICCOLI, MD, ALBERT D. PACIFICO, MD, JOHN W. KIRKLIN, MD, EUGENE H. BLACKSTONE, MD, JAMES K. KIRKLIN, MD, and LIONEL M. BARGERON, Jr., MD

One hundred thirty-seven operations (98 repairs and 39 preliminary or palliative operations) were performed for double-outlet right ventricle (DORV) with concordant atrioventricular connection from January 1967 through July 1982, with 36 hospital deaths (26%). Sixteen (12% of the total of 137 operations) of the nonrepair operations were palliative for uncorrectable malformations.

"Classic" DORV was palliated rather than repaired only when there was severe left ventricular or mitral hypoplasia or both (n = 4). Incremental risk factors for hospital death after repair of this subset for the entire period (n = 42) included young age at operation, type of repair and the era. In the current era (1978 through July 1982), 1 death (5%; 70% confidence limits 0.7 to 17%) occurred among 19 patients; the incremental risk for young age was evident only in patients <3 months old. Eleven deaths (39%) occurred among 28 patients who underwent repair of the Taussig-Bing type of DORV, with no decrease in mortality rate in the current era. Inclusion of a venous switch in the repair was the only incremental risk factor. Twenty-four patients with more-or-less normally positioned great arteries or with D-malposition but with noncommitted VSDs or complete atrioventricular canal defects underwent repair, with 7 hospital deaths; only 1 death occurred in the 11 operated upon in the current era. Four patients with DORV and L-malposition underwent repair, with no deaths. Three patients with superior-inferior ventricles and inlet VSD were considered uncorrectable and received successful palliative procedures.

Thus, results of repair in the current era are good in all subsets, even in infants, except for the Taussig-Bing heart. For this condition, a repair that does not include a venous switch is recommended. (Am J Cardiol 1983;52:549–554)

Many reports concerning the repair of double-outlet right ventricle (DORV) have failed to classify accurately the morphology of the malformation in the patients treated and the relation of this to the risks of the operation. Little cognizance has been taken in the surgical literature of the fact that some kinds of DORV are not amenable to repair and must be managed by other techniques. The results of repairs done by current techniques, including the use of cold cardioplegia, have not been separated from those of earlier periods.

From the Departments of Surgery and Pediatrics, School of Medicine and the Medical Center, The University of Alabama in Birmingham, and the Alabama Congenital Heart Disease Diagnosis and Treatment Center, Birmingham, Alabama. Manuscript received January 31, 1983; revised manuscript received May 12, 1983, accepted May 16, 1983.

Address for reprints: John W. Kirklin, M.D., Department of Surgery, University Station, Birmingham, Alabama 35294.

To define the current risks and residual problems of repair, we reviewed and analyzed our surgical experience with DORV with concordant atrioventricular connection to provide this kind of information.

Methods

Definition: For this study, we define DORV as a condition in which both great arteries arise wholly or nearly so from the morphologic right ventricle. The study includes only patients with atrioventricular concordant connection. Patients with situs ambiguus were tabulated but excluded from the analysis.

A few special situations require comment: (1) Tetralogy of Fallot is a morphologic spectrum that includes a variable amount of dextroposition of the aorta. In some cases the aorta arises >50% from the right ventricle. In this study, the malformation was considered DORV only when the aorta arose almost entirely (≥90%) from the right ventricle. (2) The

Taussig-Bing malformation (as described below) is also an entity with a spectrum, including biventricular origin of the pulmonary artery. This malformation has been considered under the heading of DORV unless the pulmonary artery arises wholly or nearly so (≥90%) from the left ventricle; then it is considered to be transposition of the great arteries with ventricular septal defect (VSD). (3) Some hearts with an anterior VSD in the outlet portion of the ventricular septum have both great arteries arising over the VSD. If >50% of both great arteries originate from left ventricle, the condition is termed double-outlet left ventricle; if both great arteries arise >50% from right ventricle, it is called DORV and is included in the study.

Material: All cases of DORV of the type described in which a cardiac surgical procedure was carried out between January 1967 and July 1982 are included in this review. All information available in the clinical records, the operative notes and, where available, autopsy reports, has been reviewed, as well as the cineangiograms from cases of uncertain morphology. Cases have been recategorized, where necessary, according to current morphologic concepts.

Morphologic categorization: The morphologic categorization is based primarily on a description of the position and interrelationships of the great arteries, and the location of the VSD in the ventricular septum and its relationship to the great arteries and the atrioventricular valves.[1,2] The great arteries were considered to be in 1 of 3 positions: (1) more-or-less normally positioned and interrelated; (2) the aorta anterior, either directly or a little to the right (the position of the great arteries in most patients with ordinary transposition of the great arteries), so-called D-malposition of the aorta; (3) the aorta to the left and side by side with the pulmonary artery. In the last 2 categories, the ascending aorta and pulmonary or trunk are parallel, whereas in the first category they are generally crossing.

The VSD as viewed from the right ventricular side is considered to be *perimembranous* when it abuts the anulus of the tricuspid valve.[3] It is categorized as being in the outlet portion of the septum when it is anterosuperior in location. It is categorized as being *trabecular* or inlet in position when it is that portion of the septum. Inlet VSD may be perimembranous (atrioventricular canal–type of VSD) or muscular. In a few cases, the VSD was part of a complete atrioventricular canal defect. Multiple VSDs were noted when present.

The VSD was further described in terms of its relation to the great arteries. It was considered to be closely related to the aortic origin (*subaortic*), closely related to the pulmonary origin (*subpulmonary*) or closely related to neither (*non-committed*).[1] Some subaortic VSDs extended anterosuperiorly and were closely related to the pulmonary artery as well, and were considered to be *doubly committed.*

Classic DORV is defined as an entity in which the great arteries are more or less normally interrelated, the VSD is perimembranous or nearly so in position and is subaortic or doubly committed. The *Taussig-Bing heart* is a form of DORV in which the aorta is anterior, sometimes to the right and sometimes to the left, and the great arteries are parallel and in the position usually found in ordinary transposition. The aortic and pulmonary valves are separated by the displaced infundibular septum, which is not interventricular. The VSD is located anterosuperiorly in the septum and is subpulmonary. Cases are accepted in which the pulmonary artery straddles the VSD and is biventricular in origin (see above).

In some patients with DORV and atrioventricular concordance, the position of the ventricles is abnormal. In cases in this study with this rotational anomaly, termed *superior-inferior ventricle*, the viscera and atria were in situs solitus, and the left ventricle was inferior and slightly posterior to the right ventricle, which was superior. An inherent part of this entity is a VSD that is in the inlet portion of the septum. In 2 of the 3 patients with this subset of DORV, a ventricular L-loop was present, yet the atrioventricular connection was concordant (criss-cross[4]). The aorta was to the left in 2 of the 3 cases. All also had pulmonary stenosis.

Analytical methods: The data were examined in simple contingency tables, and chi-square and Fisher's tests of significance were applied. Continuous variables were compared by the Student *t* test.

The incremental risk factors for hospital death were determined by logistic multivariate regression analysis for the classic and Taussig-Bing groups.[5] For the classic group, the variables examined were age, sex, ratio of right versus left ventricular enlargement, right ventricular outflow obstruction (yes or no), peripheral pulmonary artery stenosis (yes or no), restrictive (in size) versus nonrestrictive VSD, presence or absence of major associated cardiac anomalies, previous palliative operations, date of operation, cardioplegia (yes or no), atrial versus ventricular approach for the repair, surgical enlargement of the VSD (yes or no), and simple repair (which included cases in which an outflow patch limited to the right ventricular infundibulum was used) versus transanular patching versus valved extracardiac conduit. The analysis was performed for 41 patients. For the Taussig-Bing group, the same variables were examined plus presence or absence of a "venous switch" operation (Mustard or Senning repair).

Results

Among the 98 patients with DORV subjected to intracardiac repair during the 11-year period, 28 (29%) died in hospital. The overall hospital mortality was lower (18%) in the period since 1977 than in the earlier period (35%, p for difference = 0.08) (Table I). This general trend was also evident in each subset except that with the Taussig-Bing heart. Thirty-nine of the 137 operations (28%) were palliative or were for correction of a major associated cardiac anomaly (Table II).

Operations other than repair: Among the group as a whole, 3 operations were for the repair of associated cardiac malformations. Two neonates with classic DORV and an associated coarctation required initial repair of the coarctation. Both survived. One neonate with the Taussig-Bing heart died after closure of a large patent ductus arteriosus and pulmonary artery banding.

A systemic–pulmonary artery shunt was done as an initial palliative operation before later repair in 19 patients with associated pulmonary stenosis or atresia, with 3 hospital deaths (Table III). In 1971 pulmonary artery banding was done preliminary to repair in 1 patient, who survived.

Sixteen patients were considered to have uncorrectable lesions and underwent definitive palliative operations. Four patients with classic DORV had severe left ventricular or mitral hypoplasia, or both. Two of them had severely restrictive atrial septal defects and were palliated by atrial septectomy. The other 2 had associated pulmonary stenosis; 1 of these died after a Fontan repair and 1 was palliated by a systemic-pulmonary artery shunt (Table III). Two patients with the Taussig-Bing heart and severe pulmonary vascular disease were successfully palliated by a venous switch operation. Seven patients with more-or-less normally related great arteries or with D-position had inlet or trabecular (noncommitted) VSDs associated with other problems, and their defects were considered uncorrectable (Table IV). Two of these 7 patients were explored by open cardiotomy early in our experience, found to be

§ Fontan repair.

‖ Atrial septectomy plus pulmonary artery band.

AV = atrioventricular; LPA = left pulmonary artery; LV = left ventricular; PS = pulmonary stenosis; RPA = right pulmonary artery; VSD = ventricular septal defect.

uncorrectable, and open pulmonary valvotomy was done in the hopes of palliating them, but they died postoperatively. One of the 7 had a restrictive atrial septal defect and was palliated by atrial septectomy. The remaining 4 patients had pulmonary stenosis; 1 died after a Fontan repair and 3 were successfully palliated by systemic–pulmonary artery shunts. Three patients had superior-inferior ventricles and inlet VSDs. They were successfully palliated for their associated pulmonary stenosis, 2 by systemic–pulmonary artery anastomoses and 1 by open pulmonary valvotomy after intracardiac exploration.

Classic DORV: The largest morphologic subset was the group with classic DORV. As noted earlier, 4 of the 59 patients (7%) in this subset were considered uncorrectable, all because of severe left ventricular or mitral hypoplasia (Table III), or both.

Among the 42 patients who underwent repair, 15 had major associated cardiac anomalies (Table V), including 1 with congenital mitral stenosis in whom concomitant mitral valve replacement was done.

Ten hospital deaths (24%) occurred among the 42 patients with classic DORV who underwent repair between 1967 and July 1982 (Table I). Incremental risk factors for hospital death in this group, determined by multivariate logistic analysis, include young age at operation, the type of repair, and the era in which the operation was done (Table VI). The "era effect" is also evident in that from 1978 through July 1982, there was only 1 death (5%, 70% confidence limits [CL] 0.7 to 17%) among the 19 patients who underwent repair (Table VII); the patient who died was one of the 8 in this group <1 year old. The low risk in the current era (1982) is also demonstrated in a nomogram of the multivariate analysis, as is the marked decrease of the incremental risk of young age in the current era (Fig. 1). In the current era, the incremental risk of young age is not evident* unless the patient is as young as 3 months. Specifically, according to the multivariate analysis (Table VI), in the current era when a transanular patch or valved extracardiac conduit is not used, the risk of hospital death after repair in a patient 5 years old is 0.1% (CL 0.01 to 1.1%) and is 3% (CL 1 to 10%) in a patient 3 months old. The increased risk of transanular patching or a valved extracardiac conduit is also not evident in the current era (Table IV), in part because palliative shunting was used in the very young with severe pulmonary stenosis, allowing the repair to be done at an older age.

Repair of Taussig-Bing heart: Two patients with the Taussig-Bing heart were considered uncorrectable because of severe hypertensive pulmonary vascular disease, and were palliated as noted earlier.

The hospital mortality was high in those who underwent repair; 11 of 28 patients (39%; CL 29 to 51%) died in the total experience. The types of repair used varied greatly. When the repair resulted in the left ventricle ejecting into aorta, the hospital mortality was relatively low (1 death in 9 cases). Of the 19 operations in which a venous switch was included, 10 patients died. Multivariate analysis showed "inclusion of a venous switch" to be the only demonstrable incremental risk factor ($p = 0.07$).

Repair of other DORVs with more-or-less normally related great arteries: Two patients in this category and with noncommitted inlet VSDs had complete repair and survived. Six had complete atrioventricular canal defects that extended into the subaortic position, and 3 survived complete repair. Among the 5 patients in this category repaired in the current era (1978 through July 1982), 1 died.

Repair of other DORVs with D-malposition of aorta: Fifteen patients with D-malposition of the aorta but with noncommitted inlet or trabecular VSDs underwent repair, with 3 hospital deaths. One patient with D-malposition and complete atrioventricular canal defect failed to survive repair.

There were no deaths among the 6 patients in this subset operated on in the current era.

Repair of DORV with L-malposition: Of the 4 patients in this subset who underwent repair, none died.

Repair of DORV with superior-inferior ventricle and inlet VSD: Patients in this category have been considered uncorrectable.

TABLE V Surgical Correction of "Classic" Double-Outlet Right Ventricle, University of Alabama at Birmingham, January 1967 Through July 1982 (n = 42)

Major Associated Cardiac Anomalies*	No.	No. of Hospital Deaths
Multiple VSD	6	0

CL = 70% confidence limits.

Discussion

DORV is merely 1 type of ventriculoarterial connection, and thus the term embraces a wide spectrum of differing morphologies with differing surgical implications. The morphologic classification used is based on the classic paper of Lev et al in 1973[1] and the recent work of Wilcox et al,[2] and is similar to that we previously described.[6] It takes cognizance of the position of the VSD in the ventricular septum and the position of the great arteries, as well as the relation of the VSD to the great arteries.

Many reports on the results of the surgical treatment of DORV are uninterpretable because the patients are not discussed in clearly defined morphologic subsets. Also, most reports include no mention of cases not repaired, and thus fail to present an accurate picture of the limitations in the surgical possibilities for some types of DORV. This study includes a precise morphologic categorization of all cases, and reviews *all* operations, not just repairs, done for DORV in patients with atrioventricular concordant connection.

The results of repair of correctable classic DORV are now excellent, with an increased risk only in infants <3 months of age (Table VII, Fig. 1). Judson et al[7] found an increased risk in patients <5 years. We previously described the basic technique of the intraventricular tunnel repair.[6,8] The improved results in the recent era are probably related to several factors. Preoperative evaluations have been more complete, allowing more complete repairs. The operations have been more precise and efficient. The routine use of cold cardioplegic myocardial protection has probably contributed to the precision of the operation and the decreased mortality rate. An approach through the right atrium was used for the repair in many patients in this series in the current era, and this may also be helpful in achieving a low hospital mortality rate. A proper geometry for the intraventricular tunnel must not be sacrificed in using this approach. The policy of preliminary shunting in infants with severe pulmonary stenosis similar to that for the tetralogy of Fallot[9] and deferral of repair to about 3 years of age has allowed a low mortality in the current era (Table VII) even when transanular patching or a valved extracardiac conduit is required. Pertinent to this is that the risk of shunting for this malformation is as low as has been reported for tetralogy of Fallot with pulmonary stenosis.[10,11]

A few patients with classic DORV cannot have repair, usually because of severe left ventricular or mitral hypoplasia. Although the mortality rate of the Fontan repair has been high in such patients, properly done it should have an acceptable risk and should provide good definitive palliation if pulmonary vascular resistance is low.

The hospital mortality has been high in patients with the Taussig-Bing heart, and this finding has been reported by others.[12] Luber et al[13] reported only 1 death among 7 patients presumably with the Taussig-Bing heart, but this mortality rate is probably not different (p by Fisher = 0.22) from that reported here. Because of our earlier finding that most late deaths were related to pulmonary vascular disease,[6] operations in the current era have been done in patients during infancy. However, this analysis suggests that the repair should be done by some method other than the one we described earlier,[14] which includes a "venous switch" operation. The explanation is not clear for the high risk of the procedure in these infants or for the fact that it is higher than that of a similar procedure for transposition of the great arteries with VSD. In any event, 1 conclusion is that every effort should be made to do the repair in such a way that the left ventricle ejects into aorta. Only 1 death occurred among the 9 patients in which this was done. Perhaps an arterial switch operation will allow a low hospital mortality.[15] However, the more-or-less side-by-side position of the great arteries found in this subset may at times make such a repair difficult. Perhaps a more determined effort to do an intraven-

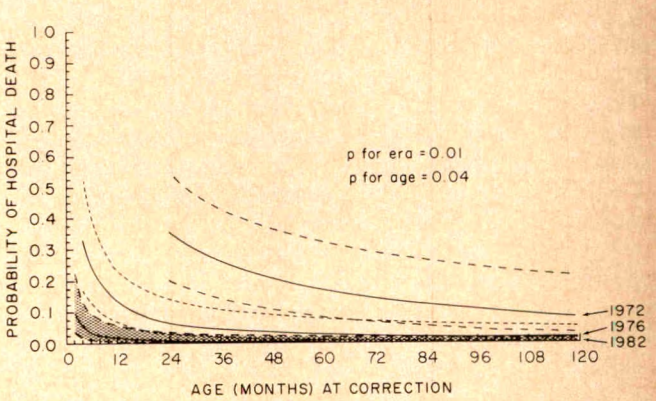

FIGURE 1. Nomogram from multivariate logistic equation (Table VI) for incremental risk factors for hospital death after repair of classic double-outlet right ventricle. The equation was solved using "use of transanular patch—No" and "use of valved extracardiac conduit—No." Three eras of operation (1972, 1976 and 1982) are plotted. The solid lines are the values obtained by solving the equation and the dashed lines enclose the 70% confidence limits. The area enclosed by the confidence limits for 1982 is stippled for ease of reference.

tricular tunnel repair between left ventricle and aorta[16,17] will be more rewarding, using a valved extracardiac conduit between the right ventricle and pulmonary artery when necessary. Because pulmonary stenosis is uncommon in the Taussig-Bing type of DORV, and because pulmonary artery banding is generally unsatisfactory, there is little opportunity to help the situation with a preliminary palliative operation.

Other DORVs with more-or-less normally related great arteries and noncommitted VSDs can usually be repaired unless there is severe left ventricular hypoplasia.[18] Ideally, the repair involves enlarging the VSD, making an intraventricular tunnel between the left ventricle and aorta, and usually placing a valved extracardiac conduit between the right ventricle and the pulmonary artery, because the intraventricular repair in this situation often blocks access to the pulmonary valve.

In the case of other DORVs with D-malposition and a VSD in the inlet or trabecular septum, which are similar to the Taussig-Bing heart except that the VSD is not in the outlet portion of the septum and subpulmonary, operation in the recent era has been performed in somewhat older patients and has carried less risk than in the case of the Taussig-Bing type ($p = 0.02$; Table I). Either type of repair (left ventricle to aorta, or one after which the right ventricle ejects into the aorta and a venous switch has been added) has allowed good results.

In patients with DORV and L-malposition, repair is easily and safely accomplished so that left ventricle ejects into aorta.[19,20] Pulmonary stenosis usually coexists in this entity and the repair is usually done after infancy. A valved extracardiac conduit between the right ventricle and pulmonary artery has been required.

DORV with concordant atrioventricular connection and a superior-inferior position of the ventricles with an inlet VSD is an uncommon malformation. Most examples of the superior-inferior ventricle are in patients with atrioventricular discordant connection, and are not represented in this report. Two of the 3 patients reported here with concordant connection had L-ventricular loop (ventricular inversion) with situs solitus of viscera and atria (criss-cross[4]). In this subset, the interposition of the right ventricle between the left ventricle and either aorta or pulmonary artery, and the position of the inlet VSD, are such as to make an intraventricular tunnel repair nearly impossible. Palliation has been elected, rather than a complex repair including a circuitous valved extracardiac conduit between left ventricle and aorta or pulmonary artery.

Karp, Whelchel, Diethelm and Bargeron (personal communication, 1982) showed that cardiac transplantation can be successful in patients with malpositioned great arteries, and the possibility of this form of definitive treatment at age 10 to 12 years must be kept in mind for children with uncorrectable types of DORV. Therefore, whatever method of palliation is used, the right and left pulmonary arteries should be left in continuity and the great arteries as undeformed as possible.

Surgical Anatomy of Double-Outlet Right Ventricle—A Reappraisal

ROBERT H. ANDERSON, MD, MRCPath, ANTON E. BECKER, MD, BENSON R. WILCOX, MD, FERGUS J. MACARTNEY, MB, BChir, FRCP, and JAMES L. WILKINSON MBChB, MRCP

In light of the recent developments in surgical treatment of double-outlet right ventricle, the anatomic observations on this lesion were reevaluated. For this review, double-outlet right ventricle was diagnosed when more than half of both arterial valves were connected to the same ventricle, although appreciating the reasons for using, in a clinical context, a "90% rule" rather than the "50% rule" used in this review. Although this ventriculoarterial connection can exist with any segmental combination, most often it is found in the setting of usually arranged atrial chambers (solitus) and atrioventricular concordance. Categorization of this subset is then done on the basis of the relationships of the arterial trunks. Three main groups stand out: intertwining arterial trunks and "normally related" arterial valves, and parallel trunks, but with the aortic valve to the right side or left side. These groupings give information concerning the site of the ventricular septal defect, which in any group may be perimembranous, muscular or be doubly committed and subarterial. Infundibular morphology is also variable, and the proximity of the arterial valves to the roof of the defect is largely determined by the extent of the ventriculo-infundibular fold.

(Am J Cardiol 1983;52:555–559)

In this issue of the Journal, Piccoli and colleagues[1] from the University of Alabama in Birmingham describe the evolution of their surgical approach to the treatment of double-outlet right ventricle (DORV). They acknowledge the significance of the classic study of Lev and colleagues[2] in influencing their classification, and also refer to our own anatomic study[3] in molding their approach to this malformation. We have been mutually influenced by their surgical experience. Several lengthy discussions with the Birmingham group since the publication of our paper have led to subtle but significant shifts of emphasis in our understanding of the morphology of DORV. In the face of these changes and the accompanying surgical report,[1] it seems appropriate to summarize briefly our current views, concentrating on the benefits they may provide for successful surgical treatment.

Definition of Double-Outlet Right Ventricle

As Piccoli et al[1] report, we define DORV in terms of a ventriculoarterial connection. In an autopsy study it is much less difficult to determine precisely the connection of overriding arterial valves to their underlying ventricles; therefore, we include within this category all hearts in which more than half of the circumference of both arterial valves are connected to the morphologically right ventricle, and thus include more anomalies than Piccoli et al within this category. However, we appreciate their reasons for using a "90% rule" rather than the "50% rule." As far as both groups of investigators are concerned, the diagnosis of DORV and tetralogy of Fallot are *not* mutually exclusive. Tetralogy of Fallot is diagnosed by its specific outflow tract morphology,[4] which can be found with either a concordant ventriculoarterial connection (aorta connected mostly to the left ventricle) or in the setting of DORV. The finding of a DORV connection does not, therefore, rule out the diagnosis of tetralogy of Fallot. Van Praagh and colleagues[5] recently argued against this approach. However, we see little advantage in a system in which diagnoses must change according to whether or not a small bundle of infundibular musculature separates an arterial from an atrioventricular valve.

Segmental Combinations with Double-Outlet Right Ventricle

Since DORV describes only the ventriculoarterial connection, it can vary considerably in terms of the other segmental connections and associated malformations, as was pointed out by Van Praagh and colleagues.[6] Piccoli et al[1] concentrated on the most frequently encountered combination—DORV in the setting of atrioventricular concordance. Cases with atrioventricular discordance and those with a univentricular atrioventricular connection were excluded from their report. The latter groups comprise a significant number of autopsied hearts studied with DORV, but are rightly excluded from this particular surgical experience. The presence of either atrioventricular discordance, double-inlet ventricle or the absent connection variant of atrioventricular valve atresia completely alters the option for correction.

Piccoli et al[1] also excluded cases with atrial isomerism from their analysis, although tabulating several patients with this atrial arrangement. Recognition of isomeric atrial chambers is an important surgical factor. DORV is by no means an uncommon ventriculoarterial connection in this setting.[7] In the presence of right isomerism ("asplenia"), the almost invariable association with total anomalous pulmonary venous connection predominates. In left isomerism ("polysplenia"), the associated lesions are somewhat less severe but still problematic. Anomalous systemic venous connections are to be expected, particularly azygos continuation of the inferior caval vein, and a common atrioventricular valve is frequently found. The anomalous position of the sinus node also should be noted (Pillai R, Shinebourne EA, Anderson RH, Lincoln C: manuscript submitted for publication). Atrial isomerism should be diagnosed preoperatively by either cross-sectional ultrasonography of the abdominal great vessels[8] or recognition of bronchial morphology by chest radiography.[9] But irrespective of this, the surgeon can routinely exclude atrial isomerism by examining the morphology of the atrial appendages. (Pillai et al: manuscript submitted for publication).

Categorization of Double-Outlet Right Ventricle

The thrust of our earlier paper[3] was that each case of DORV warranted consideration on its own merits. This contention remains valid, but the experience of Piccoli et al shows that the anomalies can be grouped in such a way that the grouping then provides significant surgical information. We have reexamined our morphologic material in this light. As they suggest, grouping according to the relationship of the arterial trunks permits inferences to be made concerning the site of the ventricular septal defect (VSD). The concept of using the interrelationships of the ventricular outflow tracts for classification has long been advocated by de la Cruz and colleagues.[10] The value of this approach for evaluating DORV was highlighted in the studies of Angelini and Leachman[11] and Arteaga et al.[12] Although at first we doubted its significance, further experience has attested to its value. Three subgroupings stand out (Fig. 1). The most frequent arrangement is for the aortic trunk to be situated posteriorly and to the right of the pulmonary trunk and for the great arteries to spiral around 1 another as they leave the base of the heart. This is similar to the arrangement found in the normal heart. In a second large group, the great arteries do not spiral as they ascend, but run in parallel fashion with the aorta to the right. Usually the trunks are also side by side, although there may be some anteroposterior variation, depending on the size of the trunks relative to each other and the position of the heart within the chest. This group is the so-called Taussig-Bing variety. The third group, which is the rarest, has parallel trunks with the aorta anterior and to the left of the pulmonary trunk. We recently observed in life a probably unique patient

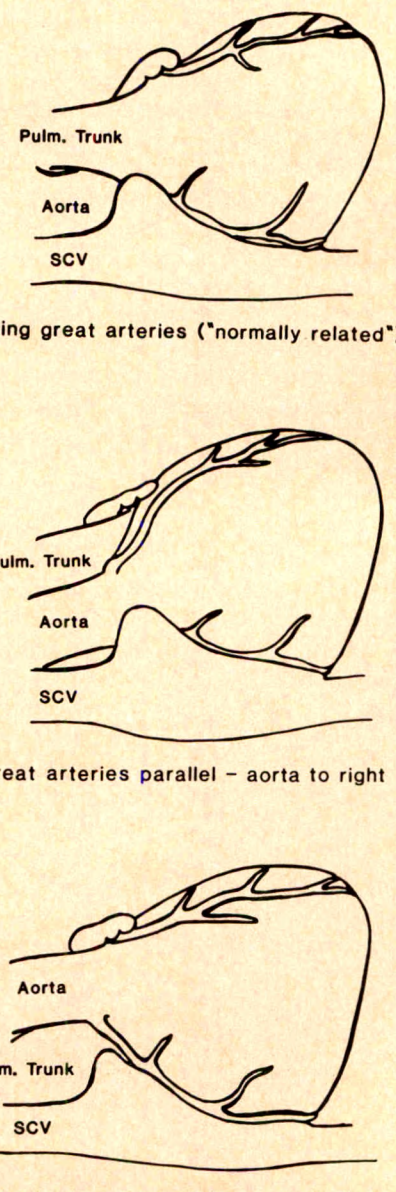

FIGURE 1. The 3 arterial relationships in double-outlet right ventricle as seen by a surgeon. Pulm. = pulmonary; SCV = superior caval vein.

with spiralling great arteries and with the aortic origin posterior and to the left of the pulmonary trunk.

These relationships of the arterial trunks have a definite bearing on the position of the VSD. A VSD is almost invariably present in DORV, and its proximity to the aortic valve is the major determinant of options for surgical treatment. For this reason, previous classifications have rightly focused on the position of the defect relative to the arterial trunks.[2] However, the fact that in different hearts the defect may be subaortic, subpulmonary, doubly committed or noncommitted should not be interpreted in terms of the defect "jumping around" within the septum.[13] Most frequently, the position of the VSD within the septum is standard—cradled between the limbs of the septomarginal trabecula (septal band, Fig. 2). The variability in position relative to the great arteries then depends on the arrangement of the arteries themselves and the orientation and size of the outlet septum. Further differences devolve on the precise morphology of the other muscular or fibrous structures that surround the VSD and form its edges.[14] In this respect, the muscular ventricular septum in hearts with DORV has only inlet and trabecular components. When both great arteries are connected to the right ventricle, the outlet part of the septum ("conal" or "infundibular" septum) is, by definition, an exclusively right ventricular structure.

Morphology of the Ventricular Septal Defect Relative to Arterial Position

Almost without exception, the VSD is cradled between the limbs of the septomarginal trabecula. The rare exceptions are muscular inlet or apical trabecular defects, or when a perimembranous VSD extends posteriorly to occupy mostly the inlet septum. These are the arrangements that produce noncommitted defects, and they can be found in hearts with any arterial relationship. Its relation to the great arteries depends on 2 further factors: the interrelations of the arteries themselves and the morphology and orientation of the outlet septum.

When the great arteries are more or less normally related, then, as shown by Arteaga et al,[12] the line dissecting the 2 arterial valves in their short axis is parallel to the ventricular septum (Fig. 3 left). The outlet septum is then positioned at right angles to the septum. In this arrangement, the outlet septum almost always fuses with the anterior limb of the septomarginal trabecula. The VSD, cradled within the limbs of the trabecula, is thus channeled so as to become subaortic. Rarely the outlet septum itself may be grossly hypoplastic or completely absent. In these circumstances, the defect between the limbs of the trabecula becomes doubly committed. With more or less normally related great arteries, therefore, the defect is usually subaortic, sometimes doubly committed and rarely noncommitted. We have not seen an exclusively subpulmonary defect in this setting.

When the great arteries are more or less parallel with the aorta to the right (the Taussig-Bing group), there is a significant difference of the alignment of the long axis of the arterial valves relative to the septum (Fig. 3 right). The line dissecting their short axis is parallel to the ventriculo-infundibular fold between tricuspid and arterial valves rather than to the septum. Only the left-sided pulmonary trunk is adjacent to the defect in

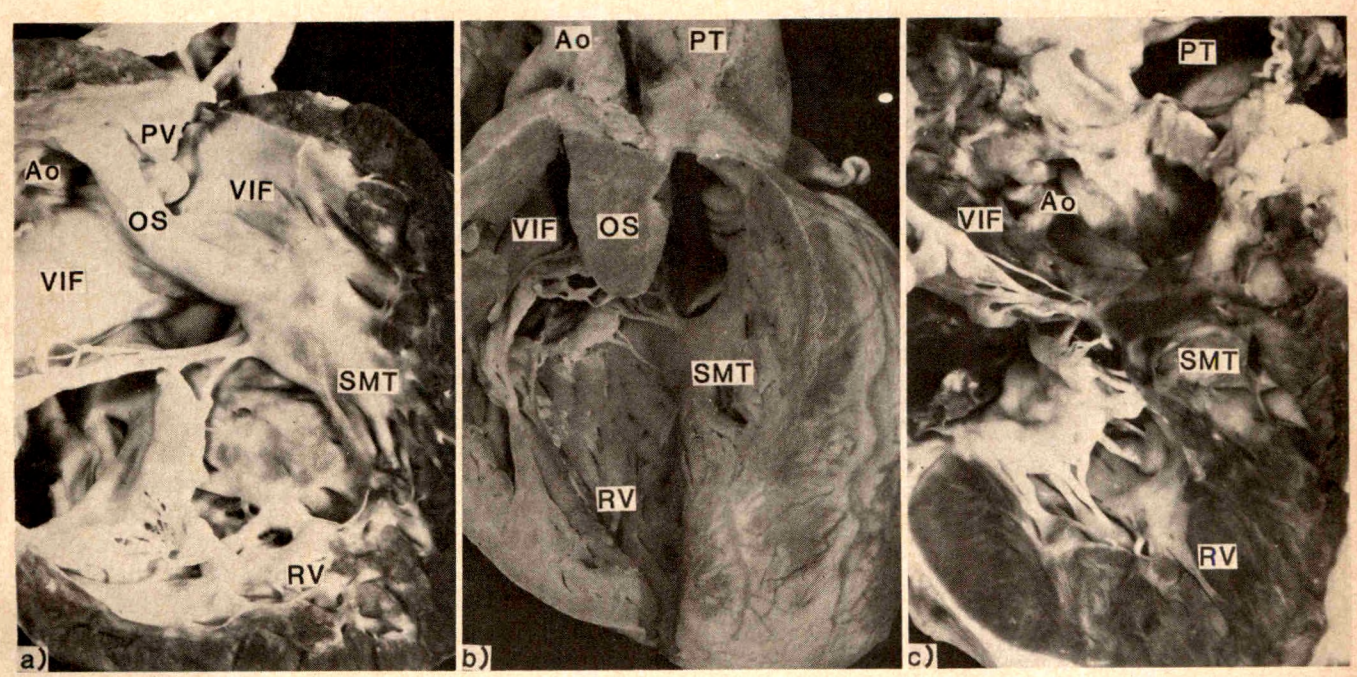

FIGURE 2. The ventricular septal defect in double-outlet right ventricle: **a**, in subaortic, **b**, in subpulmonary, and **c**, in doubly-committed subarterial positions. In each case the defect is between the limbs of the septomarginal trabecula (SMT); it is the attachment of the outlet septum (OS) relative to the ventriculo-infundibular fold (VIF) that varies. The outlet septum is absent in the heart with the doubly-committed defect. RV = right ventricle; Ao = aorta; PT = pulmonary trunk; PV = pulmonary valve.

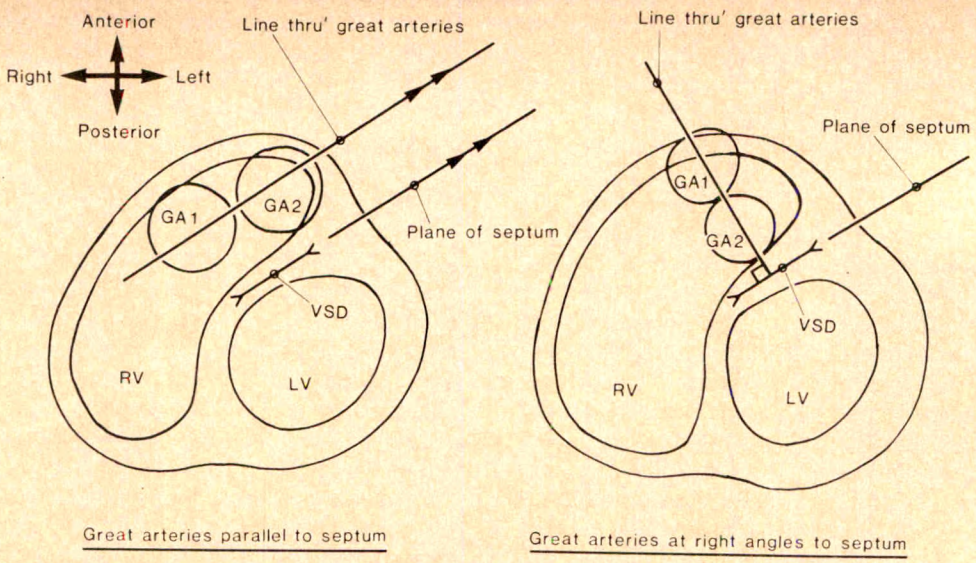

FIGURE 3. The basic difference between the relationship of the arterial trunks and the septum when the great arteries are "normally related" (**left panel**) or when the right-sided artery (almost always the aorta) is anterior (**right panel**). In the latter arrangement, only the posterior and left-sided artery is adjacent to the ventricular septal defect.

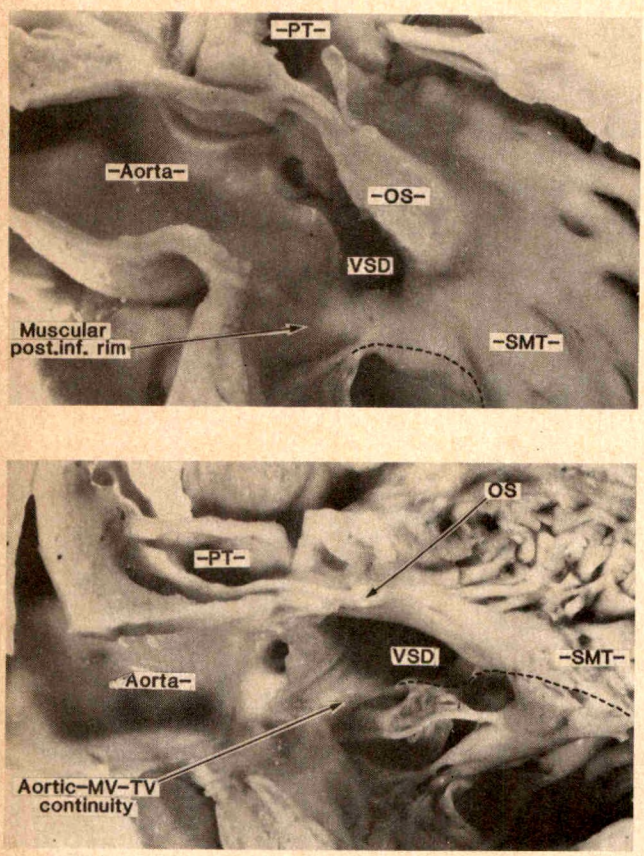

FIGURE 4. Comparison of two subaortic defects. **Upper panel,** the posterior limb of the septomarginal trabecula (SMT) fuses with the ventriculo-infundibular fold to produce a muscular postero-inferior (post. inf.) rim and protects the conduction axis (dotted line). **Lower panel,** these structures are discontinuous so that the defect is perimembranous and the conduction axis is much closer to the rim. OS = outlet septum; PT = pulmonary trunk; VSD = ventricular septal defect; MV = mitral valve; TV = tricuspid valve.

the limbs of the septomarginal trabecula. Thus, fusion of a well-formed outlet septum with the ventriculo-infundibular fold confines the defect to subpulmonary position. Much more rarely, the outlet septum may be absent or hypoplastic and the defect may then be doubly committed.

When the aorta is to the left of the pulmonary trunk, usually the long axis of the 2 arterial valves is parallel to the septum. The most usual arrangement then is for the outlet septum to fuse with the ventriculo-infundibular fold or else be hypoplastic so that the defect is either subaortic or doubly committed. When the defect is doubly committed, there is a tendency for both arterial valves to override, and a spectrum is seen extending toward double-outlet left ventricle. Brandt et al[15] called this "double outlet both ventricles." With a left-sided aorta, the outlet septum may also fuse with the anterior limb of the septomarginal trabecula, so examples can be found with the defect channeled to the posteriorly located and right-sided pulmonary trunk.

Significant Variables in the Boundaries of the Defect

In most examples of DORV, the floor of the VSD is composed of the 2 limbs of the septomarginal trabecula. Its right and left borders may be the outlet septum, the parietal ventricular wall or the ventriculo-infundibular fold, depending on whether the VSD itself is subaortic, subpulmonary or doubly committed (Fig. 2). Further variation depends on the morphology of the ventriculo-infundibular fold itself. When this muscle fold, which by definition interposes between an arterial and an atrioventricular valve,[16] is fused with the posterior limb of the septomarginal trabecula, then the VSD has a muscular postero-inferior rim. This is important to the surgeon because the muscle bundle so formed protects

the conduction tissue axis. In contrast, when the posterior limb does not extend to the fold, then irrespective of the dimensions of the fold itself there will be tricuspid-to-mitral valve fibrous continuity and the defect will be perimembranous (Fig. 4). The conduction tissue axis is then much more vulnerable in the postero-inferior margin of the defect.

The dimensions of the ventriculo-infundibular fold determine whether or not there is a bilateral infundibulum. Although for many years a bilateral infundibulum was considered the hallmark of DORV,[17] Lev et al[2] reported that both great arteries could arise exclusively from the right ventricle when there was arterial-atrioventricular valvar fibrous continuity. Our studies confirmed this finding.[3] This is not to say that the presence of a bilateral infundibulum has no surgical significance. When the fold is well-formed, it constitutes a significant muscle bundle that puts some distance between the VSD and the arterial valves. In contrast, when the fold is attenuated and there is atrioventricular-arterial valve fibrous continuity, the arterial valve is much closer to the defect. In the latter situation it is much easier to close the VSD so as to connect the arterial trunk above it to the morphologically left ventricle.

Conclusions

Cases of DORV can readily be categorized into 3 major subgroups according to the interrelations of the arterial trunks. Because each of these groups is associated with certain specific patterns of VSD, one can predict the relationship of the VSD to the great arteries from the relationship of the great arteries to each other. However, because no rule is perfect, it is much better to obtain each piece of information directly. Recent investigations using cross-sectional echocardiography[18,19] have demonstrated its reliability in identifying the relationship of the defect to the great arteries, and our own work,[20] presently being extended, suggests that it should be possible to recognize the presence of tension apparatus between the defect and the arterial valves, which is also of great surgical significance. Thus, there is little doubt that the categorization of DORV proposed by the Birmingham group gives considerable information for the surgeon and provides a valuable approach for analysis of surgical results. Cross-sectional echocardiography should provide the exact information needed to enable the surgeon to make all preparations and assess the options for operations before entering the operating room.

Percutaneous Balloon Pulmonary Valvuloplasty

ZUHDI LABABIDI, MD and JIUNN-REN WU, MD

Percutaneous balloon pulmonary valvuloplasty (BPV) was performed in 18 consecutive patients with valvular pulmonary stenosis (PS) with no associated cardiac defects. The patients were 11 months to 19 years of age. The balloon was positioned across the pulmonary valve and inflated to pressures of 80, 100, and 120 pounds/square inch (psi). Each inflation lasted approximately 10 seconds. Peak systolic pulmonary valve gradient (ΔP) and cardiac output were measured before and 15 minutes after BPV. There was no change in cardiac output, but all patients had an improved ΔP. The prevalvuloplasty ΔP was 81 $\pm$ 31 mm Hg, decreasing to 23 $\pm$ 11 mm Hg after BPV ($p < 0.01$). The right ventricular peak systolic pressure decreased from 106 $\pm$ 31 to 50 $\pm$ 12 mm Hg ($p < 0.01$). No pulmonary regurgitation was noted after BPV. The balloons were 12 or 15 mm in diameter, chosen according to the diameter of the pulmonary valve anulus. Pressures of 100 to 120 psi were required to achieve full inflation of the balloons. BPV also was performed in a patient with tetralogy of Fallot. Subsequent total repair provided an opportunity to observe the mechanism of the dilatation. Evidence of a small tear alongside the anterior valve raphe was noted. BPV induced a significant decrease in ΔP and may offer an alternative method for treating PS. (Am J Cardiol 1983;52:560–562)

Transluminal balloon angioplasty has been increasingly accepted as a nonsurgical technique for dilating stenotic arteries in the peripheral, renal and coronary circulations.[1–4] The recent success of transluminal balloon coronary angioplasty in adults has prompted us and others to apply this principle to children with coarctation of the aorta, pulmonary artery stenosis, and valvular pulmonary stenosis (PS).[5–8] This report describes our experience with the first 18 patients with PS who underwent a nonsurgical percutaneous balloon pulmonary valvuloplasty (BPV).

Methods

Between October 1982 and April 1983, 18 consecutive patients who were thought to have moderate or severe PS diagnosed by auscultation, electrocardiography, pulsed Doppler and 2-dimensional (2-D) echocardiography underwent cardiac catheterization, cineangiography and BPV. The patients were 11 months to 19 years old at the time of BPV. All patients had only PS with no associated cardiac defects. The mean peak systolic pulmonary valve pressure gradient (ΔP) for the entire group was 81 $\pm$ 31 mm Hg (Table I). All patients were premedicated with 0.1 ml/kg body weight of lytic solution (each 1 ml containing 25 mg of meperidine, 6.25 mg of chlorpromazine and 6.25 mg of promethazine) with a maximum of 2 ml given intramuscularly 30 minutes before the procedure.

Percutaneous right- and left-sided cardiac catheterizations and Fick cardiac output measurements were performed through the right groin. A pullback pressure recording across the pulmonary valve was performed, followed by a right ventricular cineangiogram in the right anterior oblique view. The right-sided cardiac catheter was then replaced by a No. 9Fr balloon catheter (Meditech), which was introduced percutaneously over a flexible tip 0.035-inch guidewire. All balloons used were 40 mm long. The 30-mm length was tried in 2 cases and was replaced by 40-mm balloons because the shorter balloon tended to migrate above or below the valve opening when inflated. The maximal inflatable diameters of the balloons were 12 or 15 mm—at least 1 mm smaller than the diameter of the pulmonary valve anulus as measured on the cineangiogram monitor. To avoid air embolization in the event of balloon rupture, the balloon was inflated and deflated several times outside the patient with a 50/50 mixture of saline solution and contrast medium until all air bubbles were removed. The guidewire was introduced into either the right or the left pulmonary artery and the balloon catheter passed over the guidewire until the middle of the deflated balloon was positioned fluoroscopically across the pulmonary valve. The valve position had been visualized during the right ventricular cineangiogram and marked on the monitor screen. The balloon was then inflated to pressures of 80, 100 and 120 psi. Each inflation lasted approximately 10 seconds. After each inflation, the balloon was deflated and remained so for 2 to 3 minutes before reinflation. The balloon catheter was then replaced by the previous right-sided cardiac catheter. Cardiac output and ΔP were measured again approximately 15 minutes after the BPV, when the heart rate and aortic pressures had returned to prevalvuloplasty levels. A second right ventricular cineangiogram was performed in the right anterior oblique view. The arterial and venous catheters were then

removed and a pressure bandage applied overnight. All patients were discharged the next morning and return visits were arranged.

Results

Of the 18 patients, 15 were found to have moderate or severe PS with a resting ΔP of 54 to 140 mm Hg and 3 had mild PS with a ΔP of 33, 35 and 45 mm Hg. No BPV was canceled for technical reasons. All patients had an improved ΔP after the BPV. The prevalvuloplasty ΔP for the entire group was 81 ± 31 mm Hg, and it decreased to 23 ± 11 mm Hg after BPV ($p < 0.01$). The mean cardiac output for the entire group before BPV was 4.56 ± 0.77 liters/min/m^2 and after BPV it was 4.69 ± 0.85 liters/min/m^2.

Subjective comparison of the valve opening and jet stream in the right ventricular cineangiograms performed before and after BPV demonstrated improvement in the valve opening. No patient had evidence of pulmonary valve regurgitation by auscultation and Doppler echocardiography the next day or during the 1- to 6-month follow-up period.

Pressures of 100 to 120 psi were required to achieve full inflation of the balloon. At 80 psi, the balloon assumed an hourglass shape because of the continued resistance of the stenotic valve opening. At 100 to 120 psi, the balloon became fully inflated and cylindrical in shape. When the balloon totally occluded the pulmonary valve, the aortic pressure dropped and was associated with bradycardia, a few premature ventricular beats and restlessness of the sedated patients. When the balloon was deflated, the aortic pressure returned to normal the the aberrant beats disappeared. There was a 5- to 10-minute period of sinus tachycardia after the balloon deflation. Although the balloon ruptured at a pressure of 120 psi in 4 patients, there was no evidence of embolization or ill effects. Three of the balloons that ruptured were 15 mm and 1 was 12 mm in diameter. Inspection of the ruptured balloons after the procedure showed a clean-cut lengthwise tear. On discharge and during the 1- to 6-month follow-up period, the femoral pulses were normal and equal, with no evidence of arterial or venous compromise to the legs.

Discussion

Congenital PS is a common congenital cardiac defect that comprises about 10% of all congenital heart diseases.[9] Surgical valvulotomy is well established and is indicated in moderate and severe PS.[10] Percutaneous transluminal balloon angioplasty has been helpful in certain coronary and peripheral vascular diseases and seems promising in treating PS.

Because of the stiff tapered tip of the catheter, Pepine et al[8] suggested leaving the guidewire protruding through the tip and into the pulmonary trunk to avoid perforation. By choosing catheters with a very short tip distal to the balloon and allowing the distal end of the long balloon to protrude into the left or right main pulmonary artery, the wire can be removed safely. Success in increasing the diameter of the valve opening depended a great deal on a high intraballoon pressure. At 80 psi, the balloon inflated only to an hourglass shape. At 100 to 120 psi, the balloon became cylindrical in shape, indicating that the valve had been opened or stretched to the full diameter of the balloon. This high pressure requirement also was demonstrated in vitro on excised coarctation specimens by Lock et al.[11] To avoid a false change in the ΔP, the pressure measurements after the BPV were performed when the heart rates, aortic pressures and cardiac outputs were approximately equal to the prevalvuloplasty values.

The mechanism of relief of the obstruction in BPV is not well established and may be different from dilatation of the coronary arteries or great vessels. In angioplasty of coarctation of the aorta and pulmonary arterial stenosis, Lock et al[12,13] demonstrated evidence

of tearing of the intimal and medial layers in experimental animals. In pulmonary valvuloplasty, Kan et al[7] assumed that rupture of the valve tissue was a mechanism for the dilatation. In a patient with tetralogy of Fallot not included in this report, we performed the BPV followed by total surgical repair the next day. At surgery, the pulmonary valve was bicuspid, with a tear alongside the anterior valve raphe demonstrating that the mechanism, at least in this case, was by actual tearing of the valve tissue.

BPV as described in this report may offer an alternative method for treating PS. The advantages are that it can be performed in young children when the risk of open-heart surgery is high, can be used as a palliative procedure, does not involve sternotomy, and requires only 2 days of hospitalization. Because it does not involve the use of blood, it may be helpful in treating patients with certain religious convictions.

Hemodynamic Responses to Ergometer Exercise in Children and Young Adults With Left Ventricular Pressure or Volume Overload

BRUCE S. ALPERT, MD, DARLENE M. MOES, MS, ROBERT H. DURANT, MA, WILLIAM B. STRONG, MD, and NADINE L. FLOOD, BA

This study determines (1) the hemodynamic responses to exercise in groups of young patients with either left ventricular (LV) pressure or volume overload, (2) whether these responses differed from healthy subjects when the variables of sex, age, race and body surface area were controlled (analysis of covariance), and (3) whether any of the exercise variables could predict noninvasively the severity of the gradient in aortic valve stenosis (AS). We tested 137 patients, including 70 with AS, 25 with aortic isthmic coarctation, 20 with aortic regurgitation and 22 with mitral regurgitation, and compared them with a control population of 405 healthy children. The children underwent a continuous, graded, maximal test with 3-minute stages. The variables evaluated were peak heart rate, systolic blood pressure, maximal work load (kg-m/min), peak working capacity index (kg-m/min/kg body weight) and ischemia on electrocardiography.

In patients with pressure overload, the maximal exercise values for work load, heart rate and peak working capacity index were significantly different ($p < 0.05$) from control values. The patients with volume overload had higher blood pressure values than either control subjects or patients with pressure overload. Similarly, the values for heart rate in patients with volume overload were lower than values for control subjects and patients with pressure overload. No exercise variable was predictive of severity of AS. These data confirm some previous investigators' findings with respect to LV volume and pressure overload, but do not support the concept that exercise test results are sensitive and specific for the prediction of severity in AS.

(Am J Cardiol 1983;52:563–567)

Several studies have demonstrated the usefulness of exercise testing in children and young adults with various forms of congenital and acquired heart disease.[1–12] However, among the studies of controlled, graded exercise testing in children with aortic valve stenosis (AS),[1–9] there is disagreement as to the ability of exercise test data to predict the severity of the obstruction to the left ventricular (LV) outflow tract. Because exercise variables reveal the functional reserve capacities of persons, the exercise test is of critical importance for the evaluation of patients with heart disease. The following variables are frequently measured during exercise testing: blood pressure; electrocardiographic measurements, such as J-point depression and ST-segment slope; heart rate; maximal work load; and peak working capacity index.

We recently evaluated these variables during upright ergometer exercise in a biracial population of 405 healthy children.[13,14] Significant racial, body surface area–dependent and sexual differences were found for the variables studied. Other investigators have not assessed whether patients with various forms of congenital heart disease differ from normal control subjects in sex, race and body surface area. In this study we determined the hemodynamic responses to exercise in groups of young patients with LV pressure or volume overload and assessed whether these responses differed from normal when using specific control values. In addition, we sought to determine whether any of the exercise variables could be used to predict noninvasively the severity of the disease.

Methods

Patients: We performed exercise tests in 137 patients with LV pressure or volume overload who did not have a shunting lesion. The patients were selected by the child's cardiologist on the basis of the clinical need for the test. LV volume overload was present in 42 patients. Aortic regurgitation was the dominant lesion in 20 and mitral regurgitation in 22. A total

of 95 patients with LV pressure overload were studied, 70 with AS and 25 with coarctation of the aorta. The racial and sexual breakdown showed a black preponderance in acquired lesions and a white predominance in congenital lesions. The patients were 8 to 23 years old (mean ± standard deviation 14 ± 4 years).

The healthy control group of 405 persons was selected from local community centers, day camps or recreational facilities. There were 221 whites and 184 blacks. The data from these studies have been published.[13,14]

The protocol was approved by the Human Assurance Committee and either the parents or patients gave written, informed consent.

Exercise protocol: The technique of exercise testing in our laboratory has been published in detail.[13,14] The children underwent a continuous, graded maximal exercise test to exhaustion on a cycle ergometer, with each stage lasting 3 minutes. Each child was encouraged to exercise to his or her individual maximal effort.

Electrocardiography: Electrocardiographic leads V_5, aVF and V_1 were monitored simultaneously on an oscilloscope. In the healthy control subjects, only lead V_5 was monitored. The electrocardiograms were recorded during the last 10 seconds of each stage. From these tracings, the J-point displacement and the ST-segment slope were measured relative to the PR isoelectric line. This line joins the onset of the p wave to the onset of the QRS and is extended to intersect the ST segment. This method was shown in our laboratory to give a low incidence (2 to 2.5%) of false-positive tests in healthy children.[14] Positive exercise electrocardiograms were defined as those with either J-point displacement >1 mm below the PR isoelectric line, or the tangent to the ST segment, measured 60 to 80 ms after the J point, having a slope ≤0 mV/s.

Heart rate: The heart rate was determined from the electrocardiogram. The heart rate was also displayed on the exercise monitor as a guide to the technician to encourage children who claimed exhaustion at inappropriately low heart rates.

Blood pressure: The systolic blood pressure was determined manually from either arm, unless a coarctation or anomalous subclavian artery decreased the palpable pulse quality. The cuff width was at least two thirds the length of the upper arm. The blood pressure was measured during the last 20 seconds of each stage of exercise and on cessation of exercise (maximal effort).

Work load: The work loads were chosen based on body weight or body surface area, or both. The maximal work load achieved (in kilogram-meters/min) was an average of the work loads completed during the last 2 minutes of exercise. The peak working capacity index was defined as the maximal work load divided by the patient's weight in kilograms. This index is the least biased by variations in age, height or relative body weight.[15]

Severity of disease: Patients with AS were classified into the following 3 groups, based on clinical impression or catheterization data: mild—those with catheterization data showing LV-to-aorta gradients <50 mm Hg; moderate—gradients of 50 to 69 mm Hg; and severe—gradients of 70 mm Hg. If no catheterizations were performed, the clinician estimated severity based on the resting electrocardiogram, physical examination and echocardiographic findings for all the patient groups. No patient had shown severe exercise symptoms, such as syncope or ventricular arrhythmias.

Statistical analysis: The exercise variables from the healthy children were regressed on body surface area. The data were expressed as confidence bands around the regression line, giving predictive values in the 5th, 25th, 75th and 95th percentiles for each body surface area; these plots have been reported.[13,14]

The patient data were compared by an analysis of covariance, with diagnosis, race and sex as the main effects, and body surface area and age as covariates. This testing allowed the comparison between various patient groups and control subjects after the effects of race, sex, body surface area and age had been removed. The significance of these individual differences between groups was assessed with Scheffe's and Tukey's multiple comparison tests;[16] a p value ≤0.05 was considered statistically significant. The exercise variables were analyzed similarly for the patients with AS in relation to the severity of their disease (gradient).

TABLE I Hemodynamic Indexes of Exercise

Diagnosis	Systolic Blood Pressure (mm Hg)	Heart Rate (beats/min)	Maximal Work Load (kg-m/min)	Peak Working Capacity Index (kg-m/min/kg)
Pressure overload				
Aortic stenosis	144 ± 26	179 ± 13*	690 ± 276*	13 ± 4*
White males	145 ± 27	179 ± 12	662 ± 276	14 ± 4
White females	137 ± 20	179 ± 15	477 ± 223	11 ± 4
Black males	176 ± 28	178 ± 18	805 ± 327	15 ± 3
Black females	140 ± 14	175 ± 1	500 ± 141	9 ± 2
Coarctation	188 ± 47†	175 ± 19*	678 ± 250	14 ± 4
White males	180 ± 48	176 ± 17	686 ± 256	10 ± 3
White females	159 ± 55	179 ± 5	450 ± 150	10 ± 2
Black males	216 ± 37	170 ± 26	761 ± 236	14 ± 5
Volume overload				
Aortic regurgitation	189 ± 36†	170 ± 16*	599 ± 261	11 ± 3*
White males	207 ± 15	161 ± 8	750 ± 150	13 ± 2
Black males	200 ± 30	172 ± 22	731 ± 294	12 ± 3
Black females	172 ± 41	172 ± 13	431 ± 152	10 ± 3
Mitral regurgitation	154 ± 39	172 ± 19*	607 ± 235	14 ± 4
White males	165 ± 21	183 ± 14	683 ± 363	17 ± 4
White females	119 ± 9	184 ± 26	351 ± 61	13 ± 4
Black males	166 ± 46	161 ± 16	685 ± 208	13 ± 3
Black females	141 ± 12	180 ± 9	675 ± 150	15 ± 3

* Significant ($p < 0.05$) difference from control values.
† Significant difference from values in normal subjects, groups with aortic stenosis and groups with myocardial infarction.
All values are expressed as mean ± standard deviation.

Results

Because of compositional differences among the clinical groups with respect to sex, age, race and body surface area, the mean ± standard deviation of the exercise variables could not be compared legitimately without first controlling specifically for sex, age, race and body surface area. The analysis of covariance approach first assesses and removes the influences of these factors and then determines whether the patients in each clinical group differ from one another and from normal with respect to each exercise variable.

Pressure overload—aortic valve stenosis: The mean level of maximal work load achieved by the patients with AS was significantly higher than that in the control group ($p < 0.05$ by both Scheffe's and Tukey's tests) (Table I). Both the maximal heart rate and peak working capacity were significantly reduced compared with control values. However, there was no significant difference when the maximal systolic blood pressure values were compared with control values. The electrocardiogram interpretation (that is, negative or positive) was not predictive of the severity of the disease (gradient) when analyzed by chi-square testing (Table II). In addition, no other exercise variable was associated with the severity of the gradient.

Coarctation: The maximal systolic blood pressure values were significantly higher than those in the control subjects, and patients with AS and mitral regurgitation. The maximal heart rate values were significantly lower than the control values. The values for both maximal work load and peak working capacity index did not differ from control values.

Pressure overload lesions combined: When the patient groups with pressure overload (AS and coarctation) were combined, their maximal exercise values for work load, heart rate and peak working capacity index were significantly different from control values (Table III).

Volume overload—aortic regurgitation: The mean peak exercise value for systolic blood pressure was significantly higher than that calculated in the control, AS or mitral regurgitation groups (Table I). The values for heart rate and peak working capacity index were significantly lower than those recorded in the control group. The maximal work load results did not differ from control results.

TABLE II Electrocardiographic Interpretation in Patients With Aortic Stenosis: Correlation With Severity

Severity of Disease	Electrocardiographic Intrepretation	
	Normal	Abnormal
Mild	33 (69%)	15 (31%)
Moderate	12 (75%)	4 (25%)
Severe	3 (50%)	3 (50%)

* For definition of severity, see text.

Mitral regurgitation: Although the mean peak values for exercise heart rate were lower than control values, no other variable differed significantly from values in the healthy group (Table I).

Volume overload lesions combined: When the patients with either aortic or mitral regurgitation were combined, they had significantly higher maximal systolic blood pressure values than those recorded in the control and pressure overload groups (Table III and Fig. 1). Similarly, their maximal heart rate was significantly lower than that for both control subjects and patients with pressure overload. In patients with volume overload values for peak working capacity index were significantly lower than values in control subjects, but did not differ from values in patients with pressure overload.

Discussion

Previous investigators have assessed the hemodynamic and electrocardiographic responses to exercise in groups of patients with AS.[1–12] Varying results have been reported, possibly related to whether the control population for comparison was chosen appropriately,

TABLE III Indexes From Pressure and Volume Overload Groups Combined

Diagnosis	Systolic Blood Pressure (mm Hg)	Heart Rate (min^{-1})	Maximal Work Load (kg-m/min)	Peak Working Capacity Index (kg-m/min/kg)
Healthy control subjects	145 ± 26	192 ± 10	558 ± 196	15 ± 4
White males	140 ± 18	193 ± 9	642 ± 248	15 ± 3
White females	142 ± 15	193 ± 9	472 ± 13	13 ± 4
Black males	155 ± 34	191 ± 10	606 ± 182	17 ± 3
Black females	147 ± 34	191 ± 9	507 ± 123	14 ± 3
Pressure overload	154 ± 36	177 ± 15*	627 ± 270*	13 ± 4*
White males	152 ± 35	178 ± 14	668 ± 270	14 ± 3
White females	139 ± 23	179 ± 14	474 ± 213	11 ± 4
Black males	198 ± 38	173 ± 22	779 ± 264	15 ± 4
Black females	141 ± 14	175 ± 1	500 ± 141	9 ± 2
Volume overload	171 ± 41†	171 ± 18†	603 ± 245	13 ± 3*
White males	190 ± 27	172 ± 16	717 ± 251	15 ± 3

Black females	163 ± 37	175 ± 12	506 ± 186	12 ± 4

* Significant ($p < 0.05$) difference from control values.
† Significant difference from values in both normal and pressure overload groups.
All values are expressed as mean ± standard deviation.

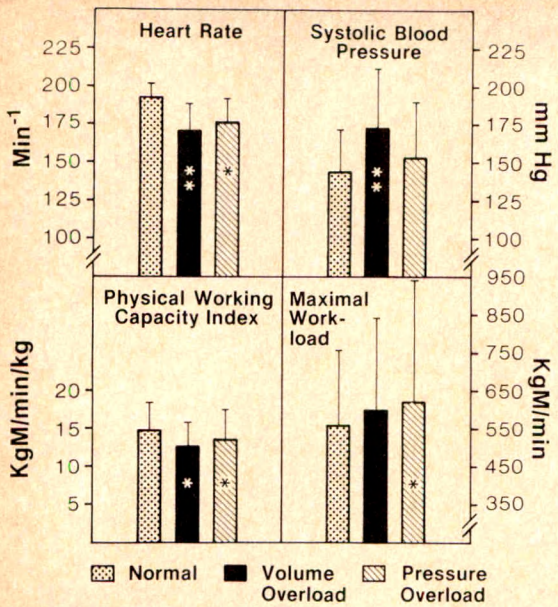

FIGURE 1. Plots of the 4 variables tested, showing the mean ± standard deviation values. * p <0.05 compared with control subjects; **p <0.05 compared with control subjects and pressure overload groups.

the method of analysis, or the variable studied. Recently, we[13,14] described the responses to exercise in over 400 healthy children. These reports defined normal values for maximal work load, peak heart rate, peak systolic blood pressure and peak working capacity index. The results of these studies stressed the necessity of using control values adjusted for sex, race and body surface area.[15] This study describes the comparison between patients with LV pressure or volume overload and specifically adjusted control values.

Blood pressure—aortic valve stenosis: James et al[5] described systolic blood pressure responses in 65 children and young adults with AS to a graded exercise ergometer protocol. Similarities also were noted in the age distribution of the subjects studied by James and those in the present study. The assessment of severity was similar; however, we did not classify the subjects with mild disease into 2 groups with a gradient <50 mm Hg. James noted that peak exercise systolic blood pressure was lower in the groups with gradients >29 mm Hg than in control subjects. The exercise blood pressure measurement did not predict further the severity of the LV to aorta gradient. Whitmer et al[4] reported that compared with preoperative values, peak exercise systolic blood pressure increased significantly postoperatively only when the preoperative gradient was ≥100 mm Hg. In patients with less severe disease, no significant changes occurred.

Previously, Alpert et al[9] showed that if systolic blood pressure increased >35 mm Hg in response to exercise, the probability of a gradient >50 mm Hg was significantly less than with an increase <35 mm Hg. However, many normal persons and patients with gradients <50 mm Hg had exercise blood pressure increases of <35 mm Hg. This limits the value of this observation to patients showing large blood pressure increases.

Blood pressure—coarctation: Several investigators have studied the use of the postexercise systolic blood pressure value in the assessment of the severity of coarctation.[17-21] These authors have stressed the striking increase in systolic blood pressure that occurs both in preoperative patients and in some patients with apparently adequate surgical results. These data suggest that the exercise test, especially with simultaneous arm and leg blood pressure measurement, is an excellent screening tool for patients who need repeat catheterization or operation, or both. The data from our patients with coarctation demonstrated significantly elevated systolic blood pressures compared with data in control subjects and patients with AS or mitral regurgitation. The patients with aortic regurgitation had systolic blood pressure comparable to those in patients with coarctation; the hemodynamic variables in these groups were vastly different. Because no variable could be chosen to accurately reflect clinical severity, we could not classify patients with coarctation into mild, moderate and severe. Similar to our findings, previous investigators[21] have concluded that exercise blood pressure is not a sensitive or specific index of noninvasive evaluation of severity.

Blood pressure—volume overload: The data from this study demonstrated significantly higher blood pressure values in patients with volume overload, but this was an artifact due to the preponderance of patients with AS in the pressure overload group.

Electrocardiography and heart rate: Early studies by Halloran[2] and Chandramouli et al[3] stressed the importance of the exercise electrocardiogram in patients with AS. Both studies reported high sensitivity and specificity for ST-T-wave changes during exercise in patients with gradients >50 mm Hg. Subsequently, Alpert et al[9] could not confirm these findings. The data from this investigation (Table II) confirm Alpert's findings that the exercise electrocardiogram is neither a sensitive nor specific tool in the identification of severity of the gradient in AS. James et al[5] demonstrated an increasing incidence of exercise-induced ST changes in 4 clinical subgroups classified by gradient measurement. For the patients with gradients <50 mm Hg, defined as mild in our series, comparable data from James' patients showed a 37.5% false-positive result. Although it may be argued that any gradient may be associated with an oxygen supply-demand imbalance and that a normal exercise electrocardiogram may be present in a patient with a severe gradient, it is generally accepted that mild gradients should not be associated with significant abnormalities on exercise electrocardiography. The data from our study tend to confirm the necessity of using the PR isoelectric line method of electrocardiographic analysis to insure a low false-positive incidence of ischemia interpretation.

Heart rate: The data from the present study show that both patients with volume overload and those with pressure overload had significantly lower maximal heart rate values than did control subjects (Tables I and III). The subjects with the highest gradients studied by James et al[5] had the lowest heart rate values (p <0.008) compared with values in control subjects. Many of our

subjects had peak exercise heart rate values of about 170 beats/min. This observation was noted by Goldberg et al.[6] We do not believe that our patients performed submaximal tests because their maximal work loads (see later) were in many instances higher than those expected from the control subjects' data. Cumming,[11] using a treadmill protocol, reported peak heart rate values in patients with congenital heart disease comparable with those in control subjects. The difference between modes of exercise (that is, cycle ergometer versus treadmill) may explain some of the apparent differences.

Working capacity: In this study we used 2 indexes of working capacity: maximal work load and peak working capacity index. DuRant et al[15] studied 5 commonly used indexes of physical working capacity and found that the physical working capacity index (kg-m/min/kg) was the least biased by age, height or relative body weight.

James et al[5] expressed their results of working capacity as the total work and the maximal work load achieved. Because the protocol was standardized for all patients, these data represent the same variable—duration of exercise. They found significant decreases in the maximal work load for all of their patient groups compared with control values. The ability of total work or maximal work load to noninvasively predict the gradient in AS was not reported.

The patients in our study with LV volume overload had the lowest values for peak working capacity index. This would suggest that they had less functional reserve capacity than did patients with LV pressure overload. This trend was noted previously[22,23] in patients of similar ages and diagnoses when they were tested doing supine exercise during cardiac catheterization.

Goldberg[10] and Duffie[12] and their associates assessed the usefulness of working capacity as an index of the degree of compromise of the patient with congenital heart disease. Most of the patients with LV pressure or volume overload had normal indexes, and no rigorous statistical analysis was reported to assess the predictive ability of these working capacity values. Cumming[11] expressed his data as the percentile ranges of minutes of exercise on a treadmill protocol compared with the minutes of exercise completed by 2 "normal" groups of children. This approach is essentially the same as that used by James et al[5] and in this study, because duration of exercise translates into a known work load. Cumming could not clearly differentiate patients with severe disease from those with mild or no disease based on this index alone.

Conclusion: The data from this report define the individual hemodynamic and electrocardiographic responses to cycle ergometer exercise and demonstrate the complex interactions of heart rate, blood pressure, working capacity and electrocardiographic interpretation. There were indications that patients with LV volume overload demonstrated more significant impairment in response to graded exercise than did patients with LV pressure overload.

Aortic Valve Replacement in Childhood: Evaluation of Left Ventricular Function by Electrocardiography, Echocardiography and Graded Exercise Testing

GEORGE S. BISSET, III, MD, RICHARD A. MEYER, MD, STEPHEN S. HIRSCHFELD, MD, FREDERICK W. JAMES, MD, DAVID C. SCHWARTZ, MD, and SAMUEL KAPLAN, MD

Preoperative and postoperative left ventricular (LV) performance was evaluated noninvasively in 15 children who survived aortic valve replacement (AVR). The noninvasive evaluation included electrocardiography, M-mode echocardiography, and graded exercise testing. Clinically, there was dramatic improvement postoperatively: All but 2 patients were asymptomatic. No conduction defects or arrhythmias were detected preoperatively; however, in the late postoperative period there was a variety of intraventricular conduction abnormalities, myocardial infarctions, and ventricular or supraventricular arrhythmias. On M-mode echocardiography, children with aortic stenosis continued to have increased LV mass postoperatively. Shortening fraction and left-sided systolic time intervals returned to normal. The children with aortic regurgitation also had persistently abnormal LV mass on echocardiography postoperatively. Exercise data indicated no improvement in working capacity after AVR. Also, 9 children (63%) continued to have ST-segment depression with maximal exercise. These data indicate that AVR does not result in a return to normal of myocardial performance in children with severe aortic valve disease.

(Am J Cardiol 1983;52:568–572)

In children, the proper timing of the replacement of a diseased aortic valve with a prosthetic or bioprosthetic device is difficult. Patients with a diseased aortic valve have long-standing left ventricular (LV) volume or pressure overload, and many have had previous unsuccessful surgical attempts at palliation. Operative mortality is high.[1–4] Complications such as perioperative myocardial infarction, low-output syndrome, cerebrovascular accidents, and conduction abnormalities are common.[4] Therefore, several considerations are important when contemplating aortic valve replacement (AVR): What was the preoperative status of LV performance? If preoperative performance was abnormal, was it normalized after surgery? How often and what types of conduction system damage were associated with AVR?

It is well documented that electrocardiography, M-mode echocardiography, and graded exercise testing are safe, reliable noninvasive methods of evaluating LV performance.[5–9] This retrospective study evaluates the changes in cardiac variables before and after AVR in children.

Methods

Patients: Fifteen consecutive survivors of AVR for aortic stenosis (AS) or aortic regurgitation (AR) between 1964 and 1980 constituted the study group. Thirteen were males and 2 females, aged 11 to 19.5 years (mean 16.3) at the time of surgery. The initial diagnosis was congenital AS in 11 patients, rheumatic AR in 2, and ventricular septal defect (VSD) with AR in 2. Persistent AS (LV-to-aortic gradient >60 mm Hg) was the reason for AVR in 6 children, predominant AR (>3+ on a scale of 0 to 4+ during aortic root angiography) in 5, and combined AS and AR in 4. Both of the children with VSDs had very small left-to-right shunts (pulmonary-to-systemic flow ratio <1.5:1).

AVR was the initial surgical procedure in 11 patients. Four with AS had undergone previous valvotomies. Thirteen mechanical and 7 bioprosthetic valves were implanted. Five children underwent rereplacement of valves. These 5 children with valve failures included the only 2 with fascia lata valves, 1 porcine xenograft, 1 Starr-Edwards, and 1 Björk-Shiley valve. The 2 mechanical valves required replacement because of patient-prothesis mismatch secondary to patient growth. In this group, all studies were performed before attempting AVR and after the most recent surgical procedure. No child has been recatheterized since his most recent AVR.

TABLE I Summary of Electrocardiograms (15 Patients)

Patient	Aortic Valve Lesion	Date of Surgery*	Preop ECG Findings	Postop ECG Findings
1	AR	12/04/79	LVH	PSVT, LVH

15	AS/AR	1/31/80	N	MVPC

* Surgical date is that of most recent procedure.
AR = aortic regurgitation; AS = aortic stenosis; CHB = complete heart block; ECG = electrocardiographic; LBBB = left bundle branch block; LVH = left ventricular hypertrophy; MI = myocardial infarction; MVPC = multifocal ventricular premature contractions; N = normal; postop = postoperative; preop = preoperative; PSVT = paroxysmal supraventricular tachycardia; RBBB = right bundle branch block; VSD = ventricular septal defect; VT = ventricular tachycardia.

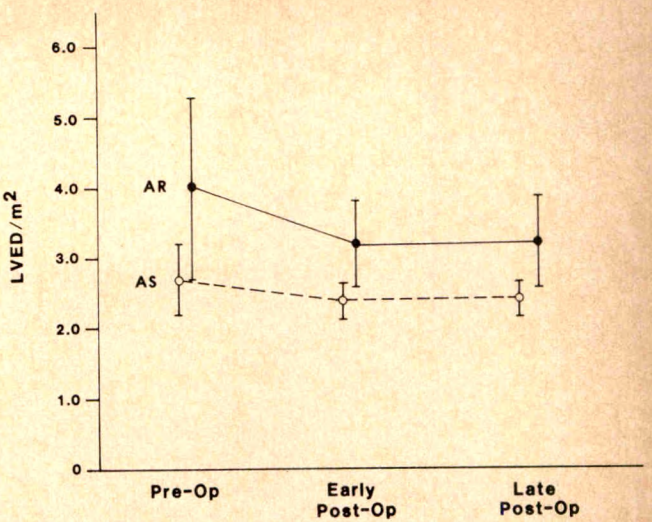

FIGURE 1. Left ventricular end-diastolic dimension index (LVED/m^2), in centimeters, in patients with aortic regurgitation (AR) and aortic stenosis (AS). Measurements were made preoperatively, early postoperatively (<2 months), and late postoperatively (>2 months). The normal index is 2.1 to 3.2 cm/m^2.

Electrocardiograms: All 15 children had standard, 12-lead electrocardiograms performed preoperatively and 2 months to 2 years postoperatively.

Each electrocardiogram was analyzed for signs of LV hypertrophy.[9] ST segments were evaluated for signs of ischemia. Any arrhythmias detected during a standard tracing were recorded on long lead 2 rhythm strips. Each tracing was also scrutinized for signs of conduction delay.

No attempt was made to quantitate changes in the degree of LV hypertrophy pre- and postoperatively because changes in conduction time make prediction inaccurate when using only voltage criteria. Also, T-wave changes (which may indicate LV hypertrophy) are difficult to quantitate.[10]

M-mode echocardiograms: Thirteen children had preoperative echocardiograms. Eleven children had early (<2 months) and late (>2 months) postoperative echocardiograms. The tracings were obtained in a manner previously described.[6] The indexes measured were: (1) LV end-diastolic index (LVEDI) = LV end-diastole/m^2 measured at the Q wave of the simultaneously recorded electrocardiogram. (2) LV preejection period (PEP)/LV ejection time (ET) ratio, measured from the aortic valve echogram.[11] The ratio was chosen rather than the absolute measurements of PEP and ET because this allowed us to make comparisons between groups, independent of differences in heart rate. (3) LV percent shortening (SF%), expressed as the percent change in the LV minor axis dimension from end-diastole to end-systole. (4) Left ventricular wall thickness index, determined by adding LV free wall and septal thicknesses, measured at end-diastole, and divided by the LV end-diastolic minor-axis dimension. (5) Septal motion, expressed as normal or abnormal (defined as deviation from the pattern of anterior motion during diastole and posterior motion during systole [<3 mm excursion]).

Exercise testing: Eleven children underwent preoperative graded exercise testing using the method described by James et al.[12] Ten children had late postoperative tests performed 2 months to 12 years (mean 3.6) after AVR. Working capacity, systolic and diastolic blood pressure responses, and electrocardiographic ST segments were evaluated. The criteria for normal values during exercise have been described.[9] Abnormal ST-segment depression was defined as ST-segment depression in the left precordial leads >1 mm, extending for ≥60 ms after the J point, below the resting P-Q junction level. The variables were measured throughout the period of exercise.[9]

Statistical analysis of all the data included unpaired Student *t* tests of preoperative and postoperative data. Paired *t* testing was not possible because of the small numbers of patients. Analysis of variance was used to determine significant differences between the groups. A p value <0.05 was considered statistically significant.

Results

Clinical data: Four of the patients were asymptomatic preoperatively. Others had complaints of chest pain, dyspnea, excessive fatigue, exercise intolerance, or a combination of these. Postoperatively, 13 patients were asymptomatic. The only 2 symptomatic children had exercise intolerance and 1 had persistent palpitations. None of the patients had murmurs of AR or VSD postoperatively, and only 3 had residual LV outflow tract systolic murmurs. No patient had systemic hypertension pre- or postoperatively at rest.

Electrocardiogram: The pre- and postoperative electrocardiographic data are presented in Table I. Ten children had signs of LV hypertrophy. In the remaining 4 patients, hypertrophy was difficult to assess because of left bundle branch block in 3 and right bundle branch block in one patient. One patient with VSD and AR and 1 with AS (who required enlargement of the small aortic valve ring) had anterolateral myocardial infarctions postoperatively. Three children presented postoperatively with documented paroxysmal supraventricular tachycardia.

The 2 patients who underwent VSD with AR repair and 2 patients in the congenital AS group now have multiform ventricular premature contractions at rest.

Echocardiography: *LVEDI (Fig. 1):* Figure 1 shows the course of the LVEDI (LV end-diastole/m^2) in the patients with predominant AS and predominant AR. The group with mixed AS and AR were classified according to the dominant lesion. The normal index varies

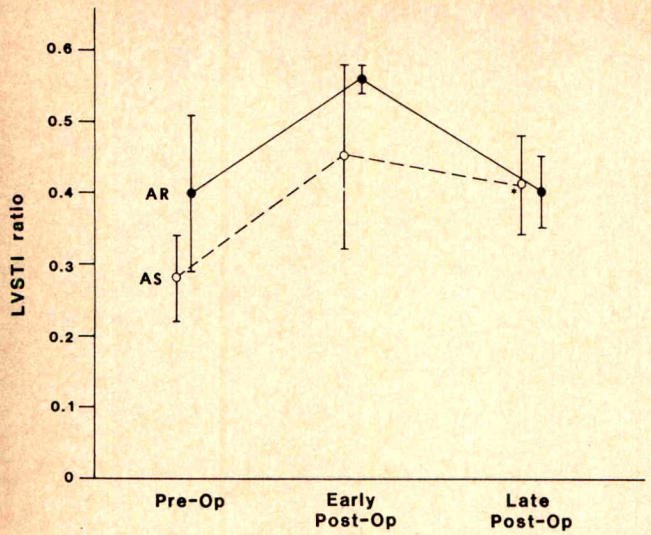

FIGURE 2. Left ventricular systolic time interval ratio (LVSTI) in patients with aortic regurgitation (AR) and aortic stenosis (AS). Measurements were made preoperatively, early postoperatively (<2 months), and late postoperatively (>2 months). *Statistically significant ($p < 0.005$) change from preoperative value. The normal LVSTI ratio is 0.30 to 0.39.

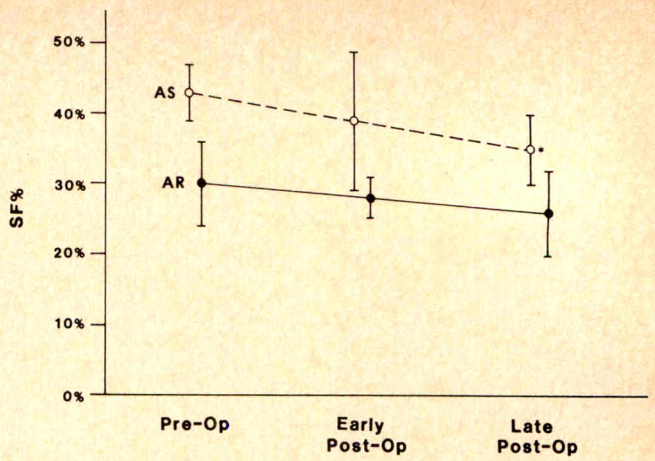

FIGURE 3. Percent left ventricular shortening (SF%) is depicted in both groups of patients (aortic regurgitation [AR] and aortic stenosis [AS]) preoperatively, early postoperatively (<2 months), and late postoperatively (>2 months). *Statistically significant ($p < 0.01$) change from preoperative value. The normal SF% range is 28 to 40%.

from 2.1 to 3.2 cm/m^2.[13] The patients with AS had normal LVEDIs (mean 2.7 ± 0.51) throughout the time course. In the group of patients with AR, the preoperative LVEDI was increased above normal (mean 4.0 ± 1.3). The LVEDI diminished slightly in the immediate postoperative period and remained at the upper limits of normal (mean 3.2 ± 0.67) into the late postoperative period. This change in dimensions was not statistically significant ($p < 0.05$).

LV systolic time interval ratio (Fig. 2): The mean LV systolic time interval (LVSTI) ratio was 0.40 ± 0.10 in the group with AR and 0.28 ± 0.06 in the group with AS during the preoperative evaluation. In the immediate postoperative period, all patients had an increased LVSTI ratio. The 2 patients with left bundle branch block were excluded from the statistics. At the late postoperative study, there was no statistically significant change in the LVSTI ratio in patients with AR. The increase in the ratio in the AS group to normal was significant ($p < 0.005$).

LV percent shortening (Fig. 3): The patients with AS demonstrated hypercontractile left ventricles preoperatively, with a mean SF% of 43 ± 4%. In the late postoperative period, the SF% returned to normal (mean 35 ± 5%). This change was statistically significant ($p < 0.01$). The patient with abnormal septal motion was excluded. The children with AR had a diminished SF% preoperatively and had no significant change in the late postoperative period.

LV wall thickness index (Fig. 4): Children with AS had high LVWTIs preoperatively (mean 0.52 ± 0.10) and did not change significantly after AVR (mean 0.52 ± 0.10). The normal value for the LVWTI is 0.32 ± 0.03 (unpublished data). In the patients with AR, the LVWTI was initially normal. There was an immediate increase in the index postoperatively, followed by a late return to near-normal values (mean 0.33 ± 0.08). The change from preoperative values was not statistically significant.

Septal motion: All patients who had preoperative echocardiograms had normal septal motion. Postoperatively, 5 patients maintained normal motion and 6 children (including all but 1 of the patients with AR) had abnormal septal motion.

Exercise testing (Table II): Preoperatively, none of the 11 patients had working capacities within 20% of expected normal. The systolic blood pressure response to maximum exercise was 12% below normal in the preoperative AS group and 13% above normal in the children with AR. Exercise diastolic blood pressure in the AS patients was generally normal and those with AR had diastolic blood pressures 19% below expected normal.

After AVR, little change was noted in the working capacity for either group. There still is not a single patient who has within 20% of the normal expected working capacity. The systolic blood pressure responses were nearly normal in both groups. The diastolic blood pressure response to maximal exercise was nearly normal in those patients with AS and was 23% above expected normal in the group with AR.

In the preoperative group, 9 of 11 had significant ST-segment depression in the left precordial leads >1 mm at maximal exercise. This included 4 of the patients with predominant AS and all 5 patients with predominant AR. Postoperatively, 4 of 8 children with AS and all 3 patients who had AR preoperatively had ST-segment depression.

Discussion

In adults, the successful correction of LV volume or pressure overload by AVR has resulted in hemodynamic and symptomatic improvement.[5,14–18] Investigators have also been concerned with evaluating the functional status of the LV myocardium after operative repair.[19] Little attention has been directed toward evaluating

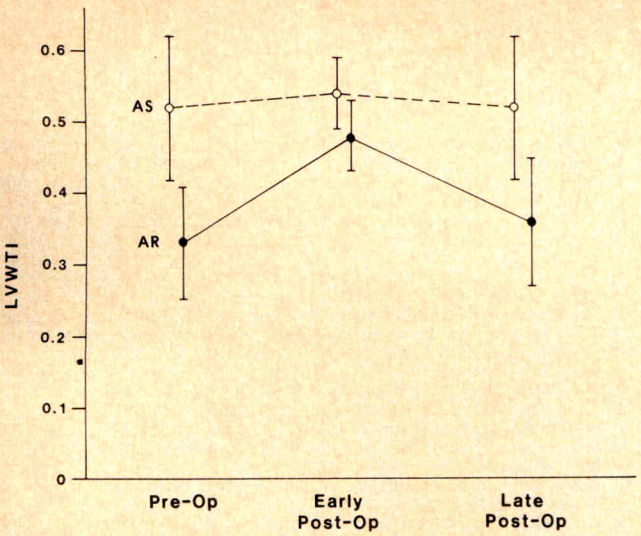

FIGURE 4. Left ventricular wall thickness index (LVWTI) plotted in both groups of patients (aortic regurgitation [AR] and aortic stenosis [AS]). See text for discussion. Preoperative, early postoperative (<2 months), and late postoperative studies (>2 months) were performed. The normal range of LVWTI is 0.29 to 0.35.

these variables in the pediatric and adolescent population.[20]

It is clear that AVR improves most patients symptomatically. Noninvasive evaluation, however, suggests residual LV abnormalities in the majority of children.

The electrocardiographic data preoperatively indicate that LV hypertrophy is the rule in children with AS or AR. Conduction abnormalities and arrhythmias were not detected, although Holter monitoring was not performed. Postoperatively, the majority of patients continue to have electrocardiographic signs of LV hypertrophy. Other abnormalities also occur, including signs of myocardial infarction, left bundle branch block, and right bundle branch block. The production of conduction defects of this type is a well-recognized problem after AVR.[21] In a study by Thompson et al,[22] preoperative conduction defects were noted in 24 to 28% of the adult patients with aortic valve disease. This contrasts sharply with our findings, in which none was demonstrated preoperatively. This might be explained by the shorter duration of volume or pressure overload before surgery, with less development of fibrosis in the area of the conduction system.

Four of the children have developed arrhythmias after surgery and 4 others have developed potentially dangerous ventricular premature contractions.[23] Why supraventricular tachycardia develops is not known. The paroxysmal ventricular tachycardia in the patient requiring aortic ring enlargement is not surprising, particularly after hypothermia and ischemic arrest.[24,25]

The echocardiographic data indicate that preoperatively, children with AS maintain efficient myocardial function by several adaptations. LV muscle mass, reflected by the LVWTI, increases with associated hypercontractility. LV end-diastolic volume is maintained at a normal level. These findings are typical of concentric LV hypertrophy. Studies in adults have suggested

TABLE II Exercise Data*

	Preop		Postop	
	AS	AR	AS	AR
Work capacity	−48%	−51%	−47%	−53%
(Normal/Total)†	(0/6)	(0/5)	(0/8)	(0/3)
SPB	−12%	+13%	−3%	+10%
(Normal/Total)	(1/6)	(4/5)	(2/8)	(2/3)
DBP	0	−19%	+9%	+23%
(Normal/Total)	(4/6)	(2/5)	(4/8)	(0/3)

* All percentages represent mean percent deviation from normal. Negative numbers indicate "below expected normal" and positive numbers indicate "above expected normal."

† First number indicates number of patients with 20% of expected normal value. Second number indicates total number of patients studied.

AR = aortic regurgitation; AS = aortic stenosis; DBP = diastolic blood pressure; SBP = systolic blood pressure.

that in patients with aortic valve disease, the LV volume is generally increased.[26] In younger children, Johnson et al[27] noted that the LV end-diastolic volume was usually decreased. The present study presents data concerning a predominantly adolescent group and perhaps represents an intermediate period in the spectrum of aortic valve disease.

After AVR, LV performance improves, but several abnormalities persist. LV mass remains increased. Although several investigators[15–18] have noted regression of myocardial hypertrophy after AVR, Baxley and Dodge[28] and Gewitz et al[20] noted little regression of LV hypertrophy after relief of obstruction. The reason for the incomplete regression of myocardial hypertrophy is unknown. Carroll et al[29] speculated that in the adult population, causes for a lack of regression could include systemic hypertension or patient-prosthetic mismatch (resulting in obstruction to LV outflow). In this group of children, no child had systemic hypertension at rest. However, the question of size mismatch is important. Since none of the patients have been recatheterized postoperatively, hemodynamic measurements of LV-aortic gradients are unavailable. Certainly, the noninvasive findings in this study group indicate that repeat catheterization is important. Another important question concerning the persistence of LV abnormalities relates to the time span of the study. Myocardial preservation techniques have changed significantly since 1964. With the small number of patients in the group and the long time span, it was difficult to separate the patients for meaningful analysis of different perfusion techniques.

Since 5 patients had valve rereplacements, repeat perfusions may also have contributed to persistent abnormalities of LV performance. However, when these patients were analyzed separately, no significant differences were found in the echographic data after the first and second procedures.

The rise to normal in the LVSTI ratio postoperatively in the patients with AS is most likely related to the physical relief of the obstruction. This reduction in LV afterload also is reflected in the return of the LV %SF to normal.

The children with predominant AR present a different echographic picture. The LVEDI in these chil-

dren were significantly greater than normal and decreased only minimally after surgery. The LVWTI was maintained at near normal preoperatively, indicating the LV muscle mass and dimensions had increased proportionately. Transiently, there was an increase in the ratio postoperatively which most likely indicated a small reduction in LV dimension without a real change in mass. Late postoperatively, the LVWTI returned to normal and, in light of the greater-than-normal LV end-diastole, this would indicate a persistent increase in LV mass.

Implications of these data are that in children with severe AR, LV hypertrophy occurs simultaneously with chamber dilatation, possibly normalizing peak wall stress. These children also have depressed ventricular performance as reflected by diminished working capacity and low echographic shortening fractions. This finding has also been documented in adult and animal studies in long-standing AR.[18,30] Diminished myocardial contractility was probably also reflected by the signs of congestive heart failure in 4 of the 5 patients with predominant AR. After AVR, there was little change in chamber size or thickness. Because most patients with AR have abnormal septal motion postoperatively, overall changes in myocardial contractility are difficult to evaluate.

The exercise data indicate that in both groups of patients there was no improvement in exercise work capacity after AVR. These patients, however, undertook no attempt at conditioning and since exercise capacity was limited for a long period of time before surgery, a great change postoperatively might not be expected.

The lower-than-expected preoperative maximum exercise systolic blood pressure in the group with AS was not surprising. Postoperatively, there was a great deal of scatter in the systolic blood pressure responses in this group; however, the mean was close to normal. The fact that only 2 of 8 patients had a maximal systolic blood pressure within 10% of the normal range suggests persistent LV dysfunction.

In the group with AR, the preoperative maximum exercise blood pressure responses are as would be predicted, with elevated systolic and low diastolic pressures. Postoperatively, only 3 of these patients were exercised, so conclusions are limited.

Preoperative maximum exercise ST segments were depressed >1 mm in 82% of the patients. This was presumably based on a major imbalance in the oxygen supply-demand ratio in the subendocardial region of the myocardium.[9] This response is similar to that illustrated by others[31] in patients with severe AS and AR.

A significant proportion of the children continue to have ST-segment depression with maximum exercise postoperatively. The reason for this finding is not clear. Patients with AS and AR continue to have an increase in LV mass, perpetuating an imbalance in the oxygen supply-demand ratio.

AVR in children, although an uncommon procedure, is an important part of the surgical therapy for severe aortic valve disease. The procedure may be well tolerated in this age group.[32] However, noninvasive evaluation raises questions as to the recoverability performance after AVR.

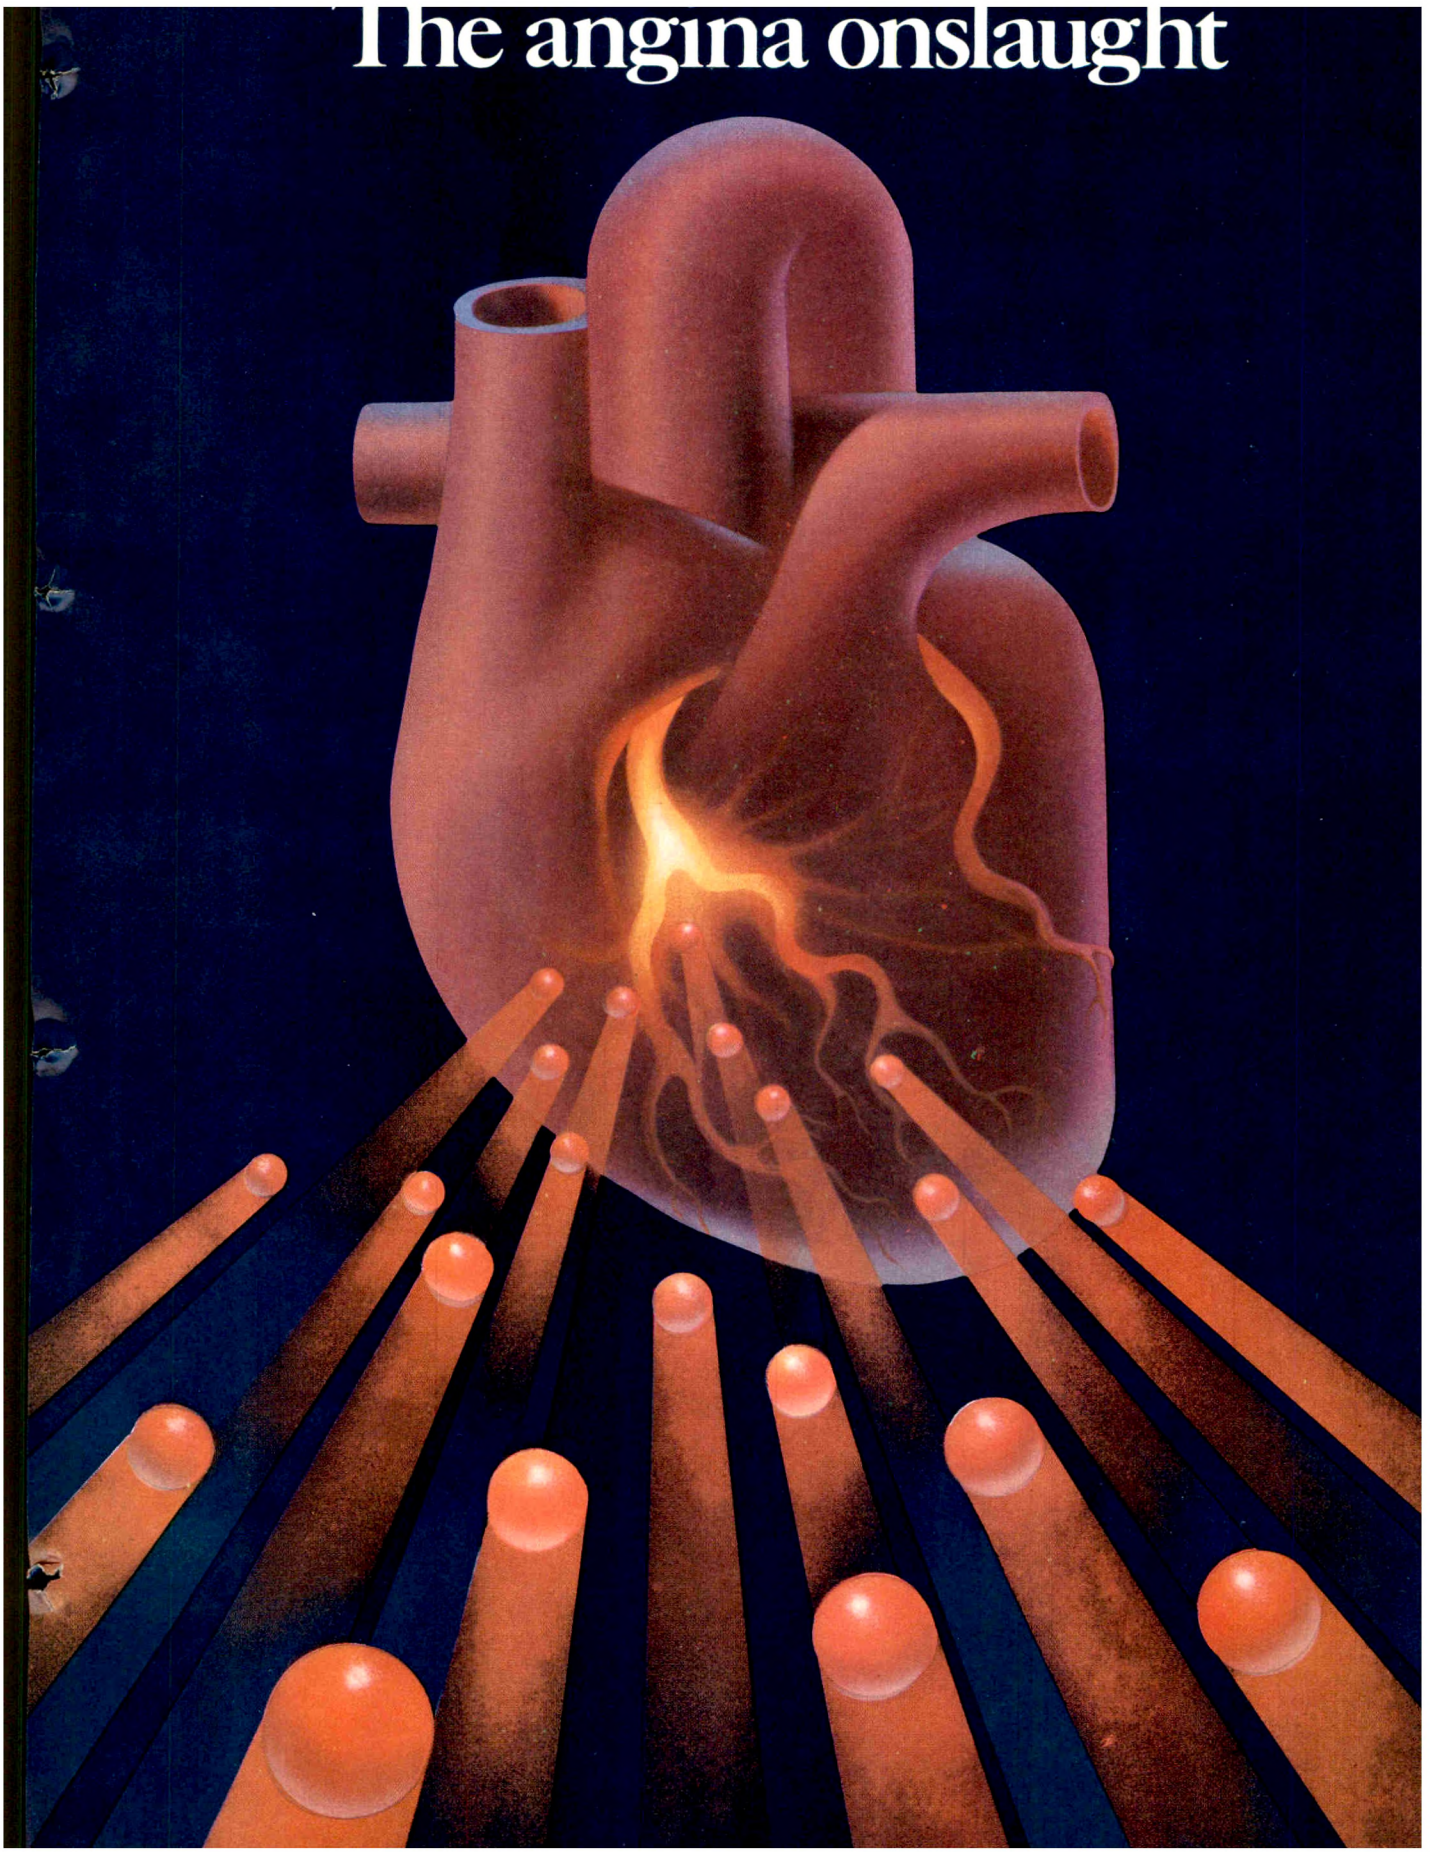
The angina onslaught



The angina shield: CORGARD® (nadolol tablets)

SQUIBB®

with other antianginal therapies
• Corgard, once a day, is as effective as propranolol, qid,[1] and is less likely to cause disturbing CNS side effects*
• Corgard provides more predictable efficacy and consistent duration of action than long-acting nitrates[2]
• Corgard offers an excellent side-effects profile, with few reports of sexual dysfunction or postural hypotension*
*For a complete discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, see prescribing information.
Apparently preserves renal circulation
"... the present demonstration of redistribution of blood flow to the kidney during therapy with nadolol may be an important exception to the findings with other beta-blocking drugs."[3]
CORGARD
(nadolol tablets)
Shields the heart, all day, every day
Please see next page for brief summary

CORGARD®
(nadolol tablets)
Once a day for angina pectoris

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System —** Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory —** Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal —** Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous —** Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System —** reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal —** mesenteric arterial thrombosis; ischemic colitis. **Hematologic —** agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic —** fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous —** reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet, in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

Double-Inlet Left Ventricle with Rudimentary Right Ventricle and Ventriculoarterial Concordance

ROBERT H. ANDERSON, MD, MRCPath, CORA C. LENOX, MD, JAMES R. ZUBERBUHLER, MD, SIEW Y. HO, PhD, AUDREY SMITH, M Phil, and JAMES L. WILKINSON, MB, ChB, MRCP

Seven hearts were studied that had in common the segmental combination of double-inlet left ventricle, rudimentary right ventricle and ventriculoarterial concordance. The prototype of these hearts has been described as the "Holmes heart" or "single ventricle type A1." Five of the hearts had 2 atrioventricular valves; in 1 of these the right valve was minimally straddling. The other 2 had a common valve. In 6 of the hearts the rudimentary right ventricle was obliquely situated on the anterior surface of the dominant left ventricle. The trabecular component was anterior and right-sided with the outlet components and pulmonary trunk in left-sided position. In the final case, both trabecular and outlet components of the rudimentary right ventricle were left-sided. Conduction tissue studies were performed in 2 hearts. In 1, the connecting atrioventricular node and bundle were in anomalous anterolateral position, as expected in double-inlet left ventricle. In the other, a ring-like, posterior, nonbranching bundle connected the regular node in the atrial septum to the branching bundle positioned on the anterior interventricular septum. The anatomic findings are related to the likely modes of presentation and differential diagnosis while the conduction tissue findings are discussed in the light of options for surgical repair. Thus, the term "single ventricle" is best avoided when describing hearts that unequivocally possess 2 ventricular chambers.

(Am J Cardiol 1983;52:573–577)

The anomaly usually called "Holmes heart" has long fascinated those interested in congenital cardiac malformations. First described in 1823 by A. F. Holmes[1] of Montreal, Lower Canada (sic), Rashkind[2] recently suggested that this original heart had atrioventricular valve atresia. However, examination of Holmes' text and illustration, together with study of the heart itself (by kind permission of Dr. A. Dobell), leaves no doubt that the anomaly consisted of double inlet to a left ventricle with a rudimentary right ventricle and ventriculoarterial concordance (aorta from left ventricle and pulmonary trunk from rudimentary right ventricle). Dr. Holmes wrote, with considerable prescience, that his case "might be classified among cases of imperfect double heart, yet it may perhaps be more correctly considered intermediate between them and those of single heart, as from the relations and small capacity of the right ventricle, it can be looked upon only as the commencement of the pulmonary artery."

These comments are still valid in light of the disagreements concerning the propriety of double-inlet ventricle as the criterion of a single ventricle[3,4] and the relation of these hearts to those with tricuspid atresia.[5] In considering these points, the disposition of the atrioventricular conduction tissue axis could also be pertinent. In hearts with double-inlet left ventricle and ventriculoarterial discordance, it is known to be grossly abnormal, the axis originating from an anomalously located anterior atrioventricular node. In the only case of double-inlet ventricle with ventriculoarterial concordance studied histologically of which we are aware,[6] the conduction tissue axis was equally abnormal; it encircled the right atrioventricular orifice but arose from a usually situated posterior atrioventricular node. We have therefore examined the morphologic charac-

This chamber was from Case 2. Note the stenotic interventricular (IV) communication. RV = right ventricular.

teristics of cases that have double inlet left ventricle and ventriculoarterial concordance.

Methods

In the Heart Museum of the Children's Hospital of Pittsburgh, 5 hearts were found with double-inlet to a left ventricle, rudimentary right ventricle and ventriculoarterial concordance. One similar heart was found in the cardiopathologic collections of the Brompton Hospital, London, and the Royal Liverpool Children's Hospital. Each heart was examined to determine the arrangement of the atrial chambers, the morphologic characteristics of the atrioventricular valves, the size and position of the rudimentary right ventricle and the presence of other associated malformations. Two cases were studied histologically using a technique described elsewhere.[7]

TABLE I Details of Specimens Studied

Heart	Atrial Septum	AV valves	Interventricular Communication	Associated Defects
1	PFO	2 (both MV)	Stenotic	LSVC to CS
2	PFO	1 (Rt-sided Ebstein)	Stenotic	LSVC to CS
3	Intact	2 (Straddling rt)	Adequate	
4	Intact	2 (both MV)	Adequate	LSVC to CS
5	FO defect	1	Adequate	Rt juxta LSVC to CS
6	PFO	2 (both MV)	Stenotic	
7	Intact	2 (both MV)	Adequate	

AV = atrioventricular; FO defect = atrial septal defect at fossa ovalis; LSVC to CS = persistent left superior vena cava to coronary sinus; MV = mitral valve; PFO = patent foramen ovale; Rt = right; Rt juxta = right juxtaposition of atrial appendages.

Results

All 7 hearts had the atrial chambers arranged in usual fashion (solitus). Both the atrial chambers connected in their entirety (or in 1 case mostly) to the dominant ventricular chamber, which had a left ventricular trabecular pattern (Fig. 1). Five hearts had 2 atrioventricular valves, both of mitral pattern with facing squat-like "septal" leaflets that were in extensive fibrous continuity with the aortic valve. The other 2 hearts had common valves, both with 4 leaflets. The right-sided component of 1 of those valves was displaced into the ventricle along the site of the ventricular septum and showed evidence of minimal Ebstein's malformation. In all hearts there was a second anterior rudimentary ventricle that supported the pulmonary valve above a complete muscular infundibulum. It had an apical trabecular component of unequivocally right ventricular type (Fig. 2). In 6 hearts these components were obliquely oriented, with the hypoplastic trabecular component right-sided relative to the aorta, which was connected to the left ventricle, and the pulmonary valve and infundibulum left-sided (Fig. 2). In 1 heart both the subpulmonary infundibulum and the apical trabecular component were left-sided relative to the aorta. In 6 hearts the right ventricle possessed no inlet component and the septum between it and the left ventricle extended to the acute margin of the ventricular mass. In the seventh heart there was minimal overriding and straddling of the right atrioventricular valve so that

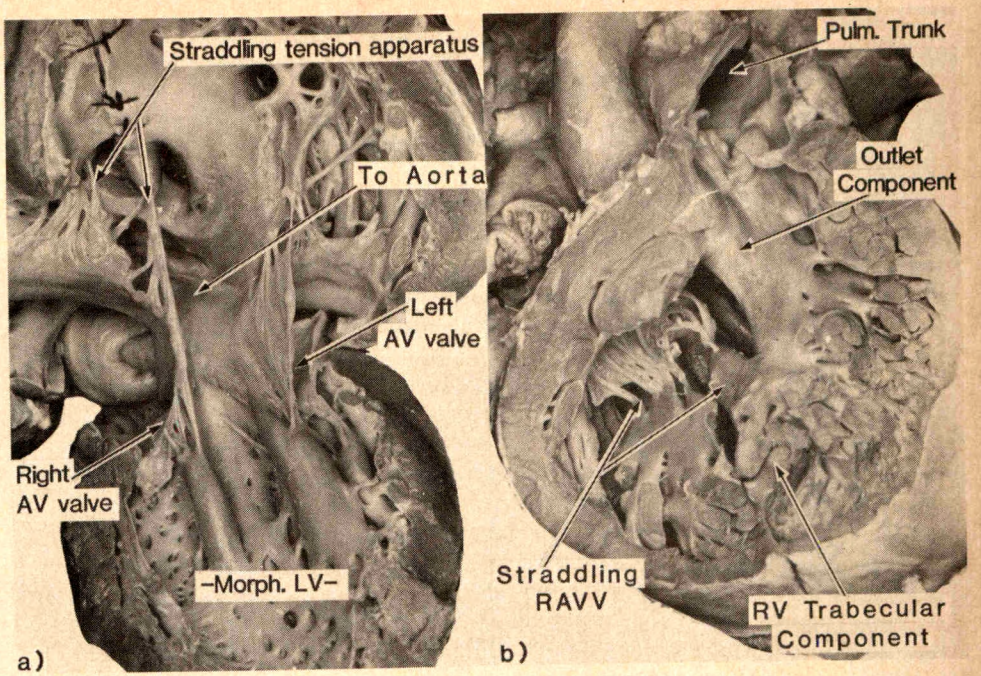

FIGURE 3. The ventricular chambers in Case 3 with minimal straddling of the right atrioventricular (AV) valve. Note the larger size of the interventricular communication and that the atria both connect exclusively to the left ventricle (LV) despite the straddling tension apparatus. **a**, the left ventricle; **b**, the rudimentary right ventricle. RV = right ventricular; Pulm. = pulmonary; RAVV = right atrioventricular valve.

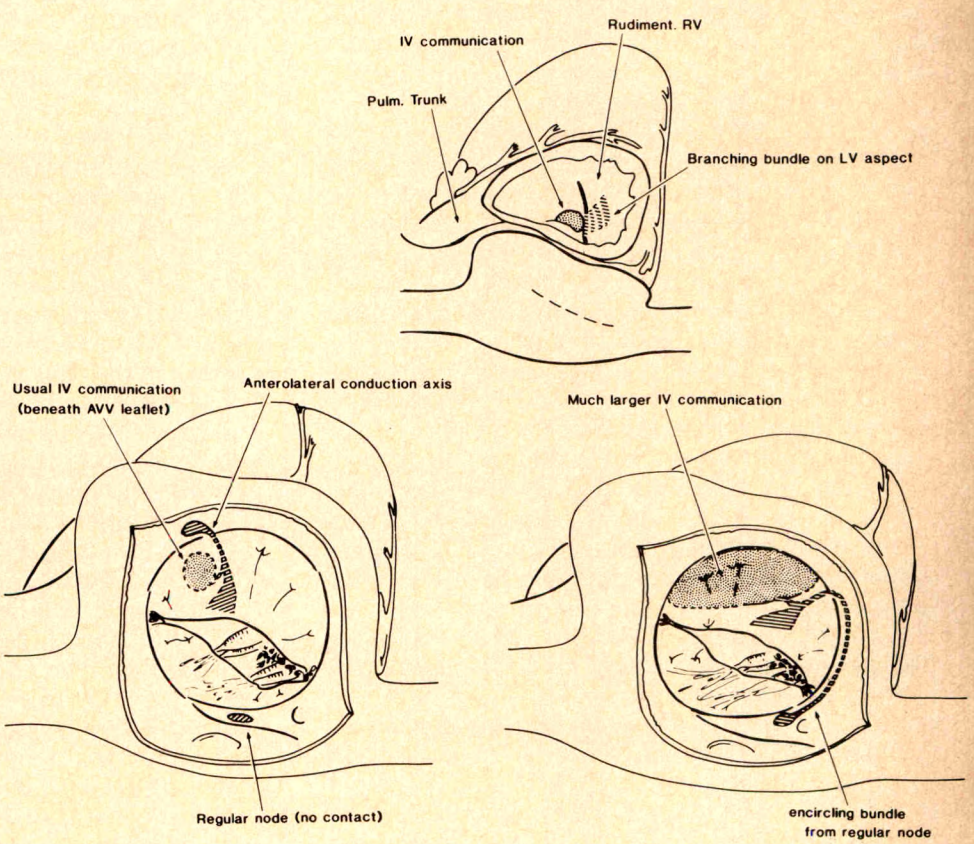

FIGURE 4. The arrangement of the conduction tissues in 2 cases. When viewed from the rudimentary right ventricle (RV), the relationship to the interventricular (IV) communication was the same in both hearts (**upper panel**). The difference would have been evident when the right valve was viewed through the right atrium (incision indicated by **dotted line** in **upper panel**). In the heart from Brompton hospital, there was an anomalous anterolateral node (**lower left**). In the heart from the Liverpool hospital, the septum approached closer to the crux, the IV communication was larger and there was an extensive bundle originating from a regular node (**lower right**). The bundle encircled the posterior aspect of the right atrioventricular orifice. AVV = atrioventricular valve.

some of the tensor appartus attached within the right ventricle (Fig. 3). The septum in this heart inserted to the atrioventricular junction between the acute margin and the crux. Additional malformations are shown in Table I.

The conduction tissue in the heart from Brompton Hospital was disposed in the anticipated fashion for double-inlet left ventricle with ventriculoarterial discordance.[8] There was an anomalous anterolateral atrioventricular node that gave rise to an anterior penetrating bundle (Fig. 4, lower left). A long, nonbranching bundle descended onto the right margin of the interventricular communication and branched beneath the septal crest on its left ventricular aspect. A left bundle branch fanned out in the smooth septal surface of the dominant ventricle and a right bundle branch

penetrated the septum to ramify in the trabecular component of the rudimentary ventricle. A regular node in the atrial septum did not give rise to a penetrating atrioventricular bundle.

The conduction tissue was quite different in the heart from the Liverpool hospital. The septum was orientated so that it fused with the atrioventricular junction much closer to the posterior surface of the heart. A long, nonbranching bundle arose from the regular atrioventricular node in the atrial septum. The bundle initially passed backward toward the crux of the heart before encircling the posterior quadrant of the right atrioventricular orifice (Fig. 4, lower right). It then ran onto the crest of the ventricular septum, where it branched, the fan-like bundle branch spreading out on the smooth left ventricular aspect of the septum and the code-like right bundle branch running through the septum into the rudimentary right ventricular trabecular component (Fig. 4, upper).

Discussion

The hearts described in this report all have both of the atrial chambers connected to the morphologically left ventricle in presence of a rudimentary right ventricle. In all cases the aorta was connected to the left ventricle and the pulmonary trunk to the right ventricle; that is, ventriculoarterial concordance was present. These hearts have been variously described in previous writings. Probably the most popular term is the "Holmes heart," although some might reserve this term for hearts with 2 separate atrioventricular valves as described by Holmes. Some hearts with this segmental combination have also been described as "displaced tricuspid orifice"[9,10] and "single ventricle type A1."[11] The anomaly is of significance with regard to its differential diagnosis, the disposition of the conducting tissues, and particularly to the ongoing discussion concerning the singularity of ventricular chambers.[4] However, although the hearts described had identical segmental combinations, they exhibited significant differences within the segmental group. Five hearts had 2 valves, 1 of these with minimal straddling, and 2 had common atrioventricular valves. Three had stenotic interventricular communications and the others had a large, adequately sized ventricular septal defect. Perhaps more significantly, 6 had the right ventricular trabecular component to the right side of the ventricular mass with the subpulmonary outflow in left-sided position and in 1, both right ventricular trabecular and outlet components were left-sided ("double-inlet left ventricle with isolated ventricular inversion"[12]).

The clinical presentation of cases with this cardiac malformation depends largely on the adequacy of the interventricular communication. If the defect is restrictive, pulmonary stenosis will result, as it does in triscupid atresia with ventriculoarterial concordance. These cases could then masquerade as tetralogy of Fallot. Diagnosis should not be a problem with cross-sectional echocardiography, which is ideal for locating absence of the inlet part of the ventricular septum, the hallmark of the anomaly.[13] When the interventricular communication is large, then the presenting feature will be failure to thrive or frank congestive heart failure. The differential diagnosis will then be a large ventricular septal defect with or without ventriculoarterial discordance ("transposition") or an atrioventricular septal defect ("endocardial cushion defect"). Again, cross-sectional echocardiography can be of great value in making these distinctions, although difficulties may be encountered in those cases with common atrioventricular valve. The key to successful diagnosis is the demonstration of the orientation of the ventricular septum.[14,15] The electrocardiogram will also be of great help in making these diagnoses.

Theoretically, the "Holmes heart" type of double-inlet left ventricle should be amenable to surgical intervention, although experience with this type of heart is limited.[16,17] However, if surgery is attempted either using septation[16,17] or a modified Fontan procedure,[18] knowledge of the precise disposition of the conduction tissue is vital. In our earlier study,[6] which has been confirmed by the present report, we were surprised to find the atrioventricular conduction axis encircling the posterior extent of the right atrioventricular orifice. This finding was unexpected, since from septal disposition we would anticipate an anterior atrioventricular node in these hearts.[6,8] Gross study of the other hearts in the present series also suggested an anterior connection, as in double-inlet left ventricle with ventriculoarterial discordance,[8] and the histologic examination in our first case confirmed this finding. These discrepancies are major problems in predicting the course of the conduction tissue. However, intraoperative mapping should enable the site of the atrioventricular conduction bundle to be determined if necessary. If a modified Fontan procedure is the chosen surgical option, then the atrioventricular node can be avoided by closing the right atrioventricular orifice with a patch secured on the right atrial aspect of the junction at least 1 cm from the valve anulus.[18]

Finally, the morphology of the hearts we are discussing is crucial to the dialectic concerning the appropriate use of the term "single ventricle." Although Ellis[3] and others unequivocally endorsed the initial suggestion of Van Praagh, Ongley and Swan[11] that double-inlet should be the criterion of a single ventricle, more recently Van Praagh, David and Van Praagh[4] altered this stance. Van Praagh and co-workers now consider only double-inlet left ventricle to be a single ventricle.[4] The hearts described in the report unequivocally have double-inlet left ventricle. There can be no doubt that they possess rudimentary right ventricles. Previously, we denied this anterior chamber ventricular status in our zeal to preserve the term "univentricular heart" and to extend its use to hearts with atrioventricular valve atresia. It is now clear to us[19] that the problems our concept produced[4] are best resolved by discontinuing the use of the term "single ventricle" to describe hearts with 2 ventricular chambers. In the present cases, they are well accounted for by the description "double-inlet left ventricle with rudimentary right ventricle and ventriculoarterial concordance." The loss of brevity is more than compensated for by the huge gain in clarity.

Pulmonary Vascular Development: Normal Values of Peripheral Vascular Structure

SHEILA G. HAWORTH, MD, MRC Path, FRCP, and ALISON A. HISLOP, PhD

Uninjected postmortem normal lung from 49 children aged 1 hour to 14 years was studied using quantitative morphometric techniques to assess arterial size, number and muscularity, particularly in the respiratory region of lung. Arterial size increased most rapidly during the first 2 months of life, but growth rate remained high during the first 4 years. At all ages, the range of values for the mean external diameter of arteries accompanying peripheral airways was considerable, but marked differences from the normal range were usually associated with a marked difference in stature. Arterial number increased rapidly in the first 2 months, but subsequently arteries multiplied at the same rate as alveoli, and the alveolar:arterial ratio was relatively constant. Mean percentage arterial medial thickness fell quickly during the first 10 days and continued to decrease during the first 3 months of life, after which there was little change. The intra-acinar arteries became more muscular during childhood as they increased in size. Vein muscle wall thickness was low throughout childhood. The normal values given in this paper provide a basis for the evaluation of lung biopsies in childhood.

(Am J Cardiol 1983;52:578–583)

In the normal child the pulmonary circulation is remodeled in the first weeks after birth as it adapts to extrauterine life. Remodeling continues throughout childhood, although more slowly.[1] The intra-acinar pulmonary arteries increase in size with growth, but also increase in number as new alveoli form. Thus, as the cardiac output increases with age, the pulmonary vascular resistance does not increase. The arteries develop a muscle coat as they increase in diameter. This sequence of events has been demonstrated using injected autopsy lung specimens.[1] Because of the difficulty in obtaining normal material, only 9 injected lung specimens were studied between 3 days and 11 years of age, and only 1 between birth and 4 months. A comparable study of arterial muscularity, size and number has not been made using uninjected tissue. Examination of uninjected lung biopsy specimens in the evaluation of patients with congenital heart disease for cardiac surgery is hampered by lack of information about lung structure in normal children of similar age.[2] Abnormalities of pulmonary arterial pressure and flow and respiratory illnesses, particularly those that cause prolonged hypoxia, can impair the development of the pulmonary circulation.

In the present study uninjected postmortem lung tissue from 49 children was examined using quantitative morphometric techniques to assess arterial size, number and muscularity, the same techniques used to study injected normal tissue. These children died between 1 hour and 14 years of age without cardiopulmonary disease, and 21 were from children <3 months old.

Materials

Lung tissue from 49 children was analyzed. Eight of the children were ≤24 hours, 2 were 6 days, 11 were 1–2 months and 28 were 3 months to 14 years old. All children <3 months had been born at term and no child died with disease of the respiratory or cardiovascular systems. The commonest cause of death was septicemia, in 39% of cases, followed by neurologic (32%), congenital abnormalities of gastrointestinal tract (13%) and malignant diseases (16%). The material was selected from patients who had died at The Hospital for Sick Children from December 1971 through December 1981. No normal lung tissue was found from neonates who died between 24 hours and 6 days of age, since most neonatal deaths were due either to a congenital abnormality of the heart or lungs or to significant pulmonary disease associated with disorders of another system. With few exceptions, lung tissue was analyzed from children who had been growing and developing normally. Eighty-five percent were between the third and 97th centile for height and 71% were at the 50th centile or above. Seven children were below the third centile and 5 died during the first 5 months of life. The male:female ratio was 1.2:1.

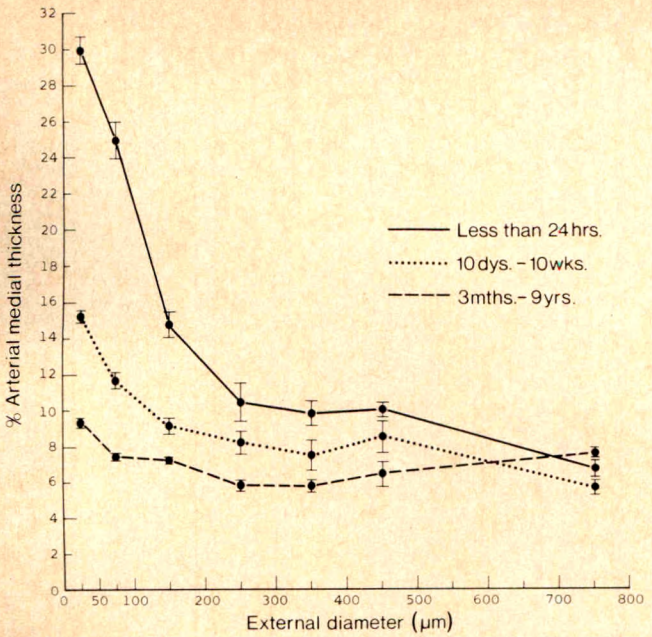

FIGURE 1. Mean percentage arterial medial thickness related to external diameter. Bars indicate the standard error of the mean.

Pathologic techniques: In the tissue studied, neither the arteries nor the airways had been injected under pressure with either fixative or other material. Blocks of tissue were taken at random and 4-μm sections were stained with Miller's stain and counterstained with van Gieson's stain or hematoxylin-eosin. The number of blocks varied according to size of the lung, from transverse sections of both lower lobes in small lungs to 10 blocks taken from each case in older children. All sections were examined qualitatively and quantitatively,[1,3,4] using different microscopes, by both investigators, and there was no significant difference in their results. In each case, arterial medial wall thickness and external diameter of all arteries containing muscle was measured and the percentage medial thickness was calculated. The arteries were grouped according to size, and for each size range the mean percentage of arterial medial thickness was calculated. The mean external diameter and structure (muscular, partially muscular or nonmuscular) of arteries accompanying terminal bronchioli, respiratory bronchioli and alveolar ducts was established.

The size and wall structure of the arteries within the alveolar walls was not studied because in normal persons, these vessels are delicate, easily compressed and may be indistinguishable from small veins. The ratio of alveoli to arteries was determined in 20 to 25 microscopic fields per case. For the veins, mean percentage muscle wall thickness was determined by measuring the thickness of the muscle coat from the internal elastic lamina to the outside of the outermost muscle cell, because there is no external elastic lamina in the normal pulmonary vein. The external diameter and wall thickness was not measured in arteries and veins that had been compressed during fixation or cutting. This reduced the number of larger vessels available for study, particularly those >400 μm in diameter.

The values for percentage arterial medial thickness were pooled into 3 groups: those from children aged ≤24 hours, those from children aged 10 days to 10 weeks and those aged ≥3 months. Differences within each age group and between the age groups were sought using the Student t test. In addition, analysis of variance and Duncan's multiple-range test for variable means was used to discriminate between muscularity in arteries of different sizes and age. To define the relationship between the size of arteries accompanying respiratory and terminal bronchioli and age a polynomial model was fitted. As the age range was from 1 hour to 14 years, log age in weeks was used as the independent variable. Upper and lower 95% confidence limits were calculated by conventional methods.[5]

The lung tissue from each case was not always suitable for the determination of all types of vascular change, as is evident from the Tables.

Results

In all specimens the alveoli had a normal appearance and were inflated, although the degree of inflation varied. None of the cases showed evidence of atelectasis or infection.

Percentage arterial medial thickness: Using the pooled data for percentage arterial medial thickness in each size range, analysis of variance of muscularity with age discriminated between the three groups and showed that percentage arterial medial thickness was significantly lower the older the patient group (Fig. 1, Table I). Duncan's multiple-range test revealed that muscularity was significantly higher the younger the patient group in all arteries <200 μm in diameter at the 5% level. In arteries 200 to 300 μm in diameter, muscularity was significantly greater in children aged 3 months to 9 years than in those ≤24 hours. Using Duncan's multiple-range test, it was not possible to discriminate between percentage arterial medial thickness and age in arteries >300 μm in diameter.

Muscularity of arteries accompanying peripheral airways: The arteries accompanying terminal

* Below third centile for height and weight.
The sex of these patients is listed in Table 2.

bronchioli were entirely surrounded by muscle cells in all but 3 cases, aged 14 hours, 4 weeks and 5 months, when 12 to 25% of the arteries were partially muscular. At respiratory bronchiolar and alveolar duct level the proportion of muscular, partially muscular and non-muscular arteries varied in children of similar age (Table II). However, a pattern of structural change with growth was discernible, the intra-acinar arteries becoming more muscular with age.

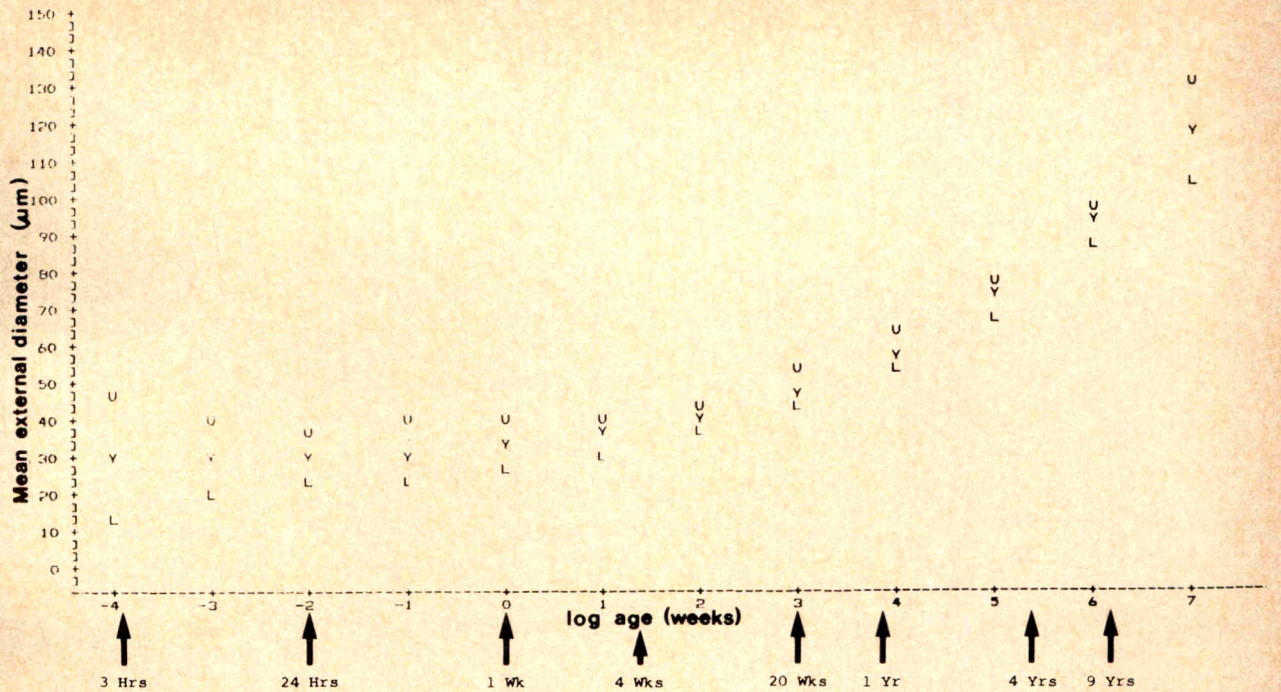

FIGURE 2. A regression line of the cubic polynomial relating mean external diameter of arteries accompanying respiratory bronchioli and age. Y = mean external diameter; UL represents the 95% confidence limits of the relationship.

Intra-acinar arterial size: Arteries accompanying terminal and respiratory bronchioli increased in size most rapidly soon after birth, particularly during the second month of life (Fig. 2, Tables III and IV). The mean external diameter of both types of artery increased steadily with age during the first 4 years, after which the arteries appeared to grow more slowly. A cubic polynomial gave a satisfactory fit to the mean external diameter of both terminal and respiratory bronchiolar arteries and age, giving a residual standard deviation of 9 μm for respiratory bronchiolar size and 27 μm for terminal bronchiolar size. Children in whom the terminal and respiratory bronchiolar arteries were markedly dissimilar in size from those in children of similar age were exceptionally tall or short for their age.

Ratio of alveoli to arteries: The ratio of alveoli to arteries was generally higher in children <8 weeks of age than in older children (Table V).

Percentage vein muscle wall thickness: Normal veins are thin-walled. Percentage vein muscle wall thickness was similar at all ages from birth to 14 years (Fig. 3, Table VI).

Discussion

In autopsy studies examination of both injected and uninjected material gives the most complete assessment of pulmonary vascular structure. However, the material available for study is frequently neither injected nor fixed in inflation. Biopsy tissue is, of course, not injected and inflation is variable.

The present study provides criteria by which to assess the development of the pulmonary circulation in uninjected, but well distended, lung biopsy or autopsy tissue. The period between birth and 2 months is the most difficult to assess the pulmonary vasculature because in normal children, the lung appears to adapt to extrauterine life at varying rates and the range of normal values is greatest at this time.

After birth, pulmonary arterial muscularity decreases at first rapidly and then more slowly, but the findings in the present study suggest that the reduction in muscularity occurs more rapidly than was previously supposed.[1,6–8] During the first 24 hours of life, muscu-

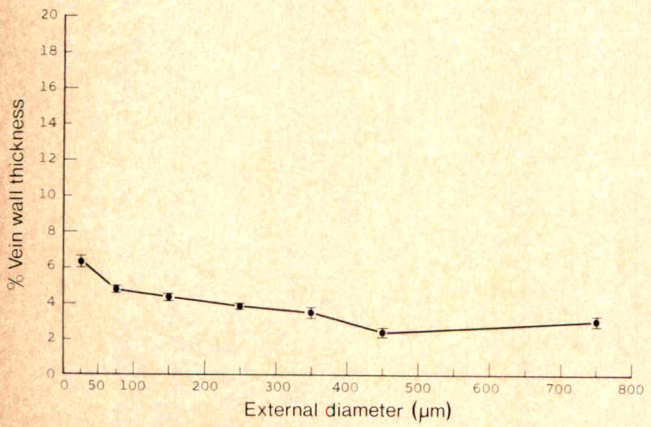

FIGURE 3. Mean percentage vein muscle wall thickness related to external diameter. Bars indicate the standard error of the mean.

larity was high in arteries of all sizes and had decreased significantly by 10 days of age, particularly in arteries <250 μm in diameter. By 3 months, muscularity was at a low mature level in arteries of all sizes. Dammann and Ferencz[6] also used uninjected tissue and found a rapid increase in luminal diameter relative to the width of the media plus intima during the first 2 to 3 months, followed by a more gradual increase. Wagenvoort et al[7] using uninjected tissue, found a rapid reduction in percentage wall thickness during the first 2 weeks of life, and then a more gradual decrease for 18 months. Naeye[8] reported a 30% reduction in medial area during the first week of life. In studies on injected lung tissue, one specimen showed a significant reduction in percentage medial thickness from the fetal level by 3 days of age in arteries <250 μm in diameter and another showed a low adult level of muscularity by 4 months.[1,3] The present study shows that in many—perhaps most—normal children, muscularity probably reaches the low mature level during the first 3 months of life.

Studies on the structure of arteries that accompany peripheral airways showed that as the respiratory bronchiolar arteries increased in size during the first year of life, they acquired a muscle coat. At alevolar duct level the size of the arteries and the proportion of nonmuscular vessels did not change significantly during the first year, suggesting the formation of new precapillary vessels. The 2 processes of formation of new arteries and muscularization of existing vessels appeared to continue until by 4 years of age, nonmuscular alveolar duct arteries were unusual. The majority of these vessels were first partially and then completely muscularized by 7 years of age. The present study suggests that the intra-acinar arteries are more muscular than was suggested in a previous study on injected material.[1] This is probably because of the injection material compressing the vessel walls and making it difficult to discern 1 or 2 smooth muscle cells in a relatively thin-walled normal artery.

The present study provides a basis for the assessment of arterial size in childhood (Fig. 2). In normal children of similar age, the arteries can differ in size, but marked differences in arterial size was associated with differences in height. When assessing a lung biopsy, a reduction in arterial size can only be confirmed when the vessels are shown to be small relative to the height and the age of the child.

The intra-acinar arteries increased in size most rapidly during the second month of life, but the rate of growth remained high during the first 4 years. These findings are similar to those in a previous study on injected tissue[1], but in that study only 6 cases were available for study between 3 days and 4 years of age. Both the injected tissue and the present uninjected tissue studies have shown a greater relative increase in size of the proximal rather than the distal intra-acinar arteries, probably because of the increase in number as well as size of more distal vessels.

The ratio of alveoli to arteries was generally higher during the first 6 months of life than later, when the alveoli and arteries appeared to develop at a similar rate. The alveolar:arterial ratio varied considerably from field to field within any one case. In the normal lung, the number of alveoli per microscopic field of tissue is relatively constant, but the concentration of arteries varies. The number of arteries per microscopic field depends on the part of the acinus being sampled and also on the plane of section. Therefore, as large a number of fields as possible should be sampled in any 1 case. An alveolar:arterial ratio obtained from a small amount of lung biopsy tissue should be interpreted cautiously. In the normal, uninjected lung, it may be difficult to determine the alveolar/arterial ratio because it may be impossible to distinguish small, thin-walled, precapillary arteries from small, thin-walled, postcapillary veins. This explains the relatively small number of results in the present study. However, this is not a problem in the lung biopsies of children with pulmonary hypertension, because the presence of medial hypertrophy makes the distinction between arteries and veins relatively easy.

The thickness of the vein muscle wall was low and did not change with age in this or in previous studies of injected material.[9] In the present study, muscle was found in veins <50 μm in diameter. Wagenvoort[10] found that in adults, muscle first appeared in uninjected veins

40–50 μm in diameter, and Hislop and Reid[9] reported similar findings in the injected lungs of 2 children aged 3 and 10 years.

The findings of the present study will help to assess lung biopsies in children. The greatest variation in arterial structure is seen during the first 3 months of life. Fortunately, relatively few children are biopsied so young. At all ages, the range of normal values is greater in uninjected than in injected material. In the abnormal lung, however, the structural changes are often pronounced and no structural feature is interpreted in isolation, but is related to the other findings in the biopsy. In the lung affected by pulmonary hypertension, for example, pulmonary arterial muscularity is usually considerably greater than normal except when the medial coat has atrophied, as is seen in pulmonary vascular disease grade III or higher;[11] then, other abnormal features are apparent in the biopsy.

The overall growth of the child must be considered when assessing the size of the intra-acinar arteries. This is particularly important in children with congenital heart disease who have severe pulmonary hypoperfusion and are small for their age. In such children, intra-acinar arterial size may be reduced with respect to both age and height.[12]

Biventricular Function in Sickle-Cell Anemia: Radionuclide Angiographic and Thallium-201 Scintigraphic Evaluation

BRUNO V. MANNO, MD, EDWARD R. BURKA, MD, A-HAMID HAKKI, MD, CATHERINE S. MANNO, MD, ABDULMASSIH S. ISKANDRIAN, MD, and ANN MARIE NOONE, RN

Left ventricular (LV) and right ventricular (RV) function were evaluated at rest and during exercise using radionuclide ventriculography in 10 patients, aged 19–53 years, with sickle-cell anemia (SCA). Seven patients were in New York Heart Association functional class I and 3 were in class II. The resting LV ejection fraction (EF) was normal in 9 patients and the resting RVEF was normal in 4. LV dilation and high cardiac output were observed in 6 patients at rest. The LVEF during exercise was normal in all 10 patients, whereas only 2 patients had normal RVEF at rest and during exercise. The LVEF was lower in patients with SCA at rest (54 ± 4% versus 61 ± 6%, p <0.001) and exercise (66 ± 4% versus 74 ± 6%, p <0.001) than in 42 age-matched normal subjects. Rest thallium-201 images from 9 patients showed abnormal RV uptake in 8 and normal LV uptake in 8.

Thus, in adult patients with SCA, LV function was normal during exercise in all patients and at rest in all but 1 patient. The LVEF, however, was lower than that in age-matched normal subjects. RV function was abnormal in most patients at rest and during exercise. RV thallium-201 uptake suggested pressure or volume overload (or both), most likely due to pulmonary vaso-occlusive complications of the disease.

(Am J Cardiol 1983;52:584–587)

Most patients with sickle-cell anemia (SCA) show evidence of cardiac dysfunction, manifested principally as fatigue, dyspnea on exertion, cardiac murmur, cardiomegaly and electrocardiographic abnormalities.[1,2] The precise pathophysiologic mechanisms of cardiac dysfunction in these patients have not been well defined. Several mechanisms have been postulated: the effect of anemia[3] per se; thrombotic occlusion of coronary circulation by sickle cells, with resultant myocardial fibrosis;[2,4] cardiomyopathy;[5] iron overload in the myocardium;[6,7] and pulmonary hypertension secondary to repeated pulmonary infarctions.[7–10] Little physiologic information is available regarding ventricular performance during exercise in patients with SCA.[11,12] The purpose of this study was to determine biventricular function at rest and during upright exercise in patients with SCA using radionuclide angiography and thallium-201 scintigraphy.

Methods

We studied 10 adult patients (6 men and 4 women aged 19 and 53 years; mean 31) with the diagnosis of homozygous SCA previously documented by hemoglobin electrophoresis. These patients had mild symptoms of fatigue, dyspnea on exertion or palpitations. A careful history was taken and physical examination was performed in each patient. None of the patients had a history of angina pectoris, associated cardiac disease or heavy smoking, and there were no physical findings of chronic obstructive lung disease. Although the exact number of transfusions could not be determined, 8 patients (all except patients 6 and 9) had multiple transfusions during childhood. Each patient underwent symptom-limited upright exercise testing; biventricular function was determined by means of first-pass radionuclide ventriculography with a computerized multicrystal camera.[13,14]

Two electrocardiographic leads (CM_5 and aVF) were monitored constantly, and the blood pressure was measured by the cuff method every minute during exercise and the recovery period. Baseline heart rate and blood pressure were recorded, and the upright exercise was begun at a work load of 200 kilopond-meters (kpm)/min, and increased by 100 kpm/min every 2 minutes until the study was completed. The end points of exercise were excessive fatigue, leg weakness or dyspnea.

The methods of exercise testing and measurement of left ventricular (LV) ejection fraction (EF), end-diastolic volume, end-systolic volume, stroke volume, cardiac output and right

↑ = increased; 0 = absent; Dig = digoxin; DOE = dyspnea on exertion; ECG = electrocardiogram; F = female; f = fatigue; Fur = furosemide; Hb = hemoglobin; Hct = Hematocrit; LV = left ventricle; LVH = left ventricular hypertrophy; M = male; Med = medications; NL = normal; NYHA = New York Heart Association functional class; P_2 = pulmonic component of second heart sound; Palp = palpitations; PRWP = poor R-wave progression; RV = right ventricle; RVH = possible right ventricular hypertrophy; SEM = systolic ejection murmur; ST-T = ST-T-wave changes.

ventricular (RV) EF have been described.[13,14] All volumes were indexed by dividing them by the body surface area.

Nine of the 10 patients also underwent rest thallium-201 imaging. The rest images were obtained in 3 projections 20 minutes after intravenous administration of 2 mCi of thallium-201. This technique has been described.[15] The thallium-201 images were assessed for the presence or absence of perfusion defects in the LV images as well as for uptake in the region of the right ventricle. The RV thallium uptake was compared with the LV uptake and graded on a scale of 0 to 3: 0 = no uptake, 1 = mild uptake, 2 = moderate uptake and 3 = severe uptake equal to that of LV uptake.

Statistical analysis: Statistical analysis was performed by analysis of variance or the Yates-corrected chi-square test for differences between groups. Differences between rest and exercise measurements were analyzed by means of a 2-tailed paired *t* test. Values were expressed as the mean ± standard deviation (SD) when appropriate. A probability (p) value <0.05 was considered significant.

Results

The pertinent clinical data for the study patients are listed in Table I.

The exercise was terminated because of fatigue in 9 patients and dyspnea in 1 patient. The exercise capacity was abnormal (<7 minutes) in 7 patients. (In our laboratory, patients with no underlying cardiovascular disease have an exercise capacity of ≥7 minutes.[16]) None had chest pain during exercise.

Left ventricular function: The resting LV function was normal (EF ≥ 50%) in 9 patients and mildly decreased in 1 patient (no. 6). The resting end-diastolic volume was increased (>100 ml/m^2) in 6 patients and was normal in 4. The exercise LVEF was normal (≥55%) in all 10 patients. The response to exercise was normal (≥5% increase) in 8 patients. One of the 2 patients with <5% increase (no. 7) had a resting heart rate of 120 beats/min; thus, the resting EF in this patient was already increased. The other patient (no. 10) had a 4% increase in EF during exercise (Table II). The LVEF was lower in patients with SCA at rest (54 ± 4 versus 61 ± 6%, $p<0.001$) and during exercise (66 ± 4 versus 74 ± 6%, $p<0.001$) than in 42 age-matched normal subjects. These subjects were 7 to 35 years old (mean 25 ± 6) and had a low probability of coronary heart disease and no other recognizable heart diseases.

There was no significant change in LV end-diastolic volume with exercise (131 ± 41 ml/m^2 at rest versus 114 ± 27 ml/m^2 during exercise; difference not significant [NS]). Individual responses are listed in Table II. The cardiac index increased in all 10 patients during exercise. Patients 3 and 9 had at least a 3-fold increase in cardiac index, Patients 1, 4, 6, 8 and 10 at least a 2-fold increase and Patients 2, 5 and 7 less than a 2-fold increase. The increase in cardiac index with exercise was mediated primarily by an increase in the heart rate, because the stroke volume did not change significantly with exercise (69 ± 20 ml/m^2 at rest versus 75 ± 14 ml/m^2 during exercise; NS).

Right ventricular function: The RVEF at rest was normal (≥40%) in only 4 patients. An increase in RVEF during exercise (≥5%) was seen in patients with normal or abnormal resting REVF. However, only 2 patients had normal RVEF at rest and during exercise. In our laboratory a normal RVEF obtained in 12 subjects is 46 ± 7% and 57 ± 9% during exercise ($p<0.001$). Of the 8 patients with a loud pulmonary component of second heart sounds or RV enlargement by physical examination (Table I), 7 had abnormal RV function at rest or during exercise (or both).

Rest thallium-201 imaging: The rest thallium-201 images showed a normal LV perfusion pattern in 8 of 9 patients. Patient 1 had a mild decrease in perfusion of the inferior wall. This patient was the oldest in the group, had a normal LVEF and wall motion at rest and during exercise, and had a normal LV size. Abnormal RV uptake (grades 1 or 2) was present in 8 of 9 patients (Fig. 1). Abnormal RV uptake was not seen in any of 60 patients who had normal rest thallium-201 images in our laboratory. The RVEF was abnormal at rest or during exercise in 7 of 8 patients with RV visualization on thallium scintigraphy. The RV uptake was mild (+1) in 7 patients and moderate (+2) in 1 patient (no. 1). Patient 9, who had no RV uptake, had not had prior transfusions and had normal LV size and a normal LVEF. This patient had a mildly decreased RVEF at rest, but a normal response to exercise.

TABLE II Resting and Exercise Hemodynamics in 10 Patients With Sickle-Cell Anemia

	Blood Pressure (mm Hg)		Heart Rate (beats/min)		LVEF (%)		RVEF (%)		EDVI (ml/m²)		ESVI (ml/m²)		SVI (ml/m²)		CI (l/min/m²)

Discussion

SCA is chronic hemolytic anemia with myriad clinical manifestations. The most common form of this hemoglobinopathy, hemoglobin SS, affects 1 in 500 black infants born in the United States.[17] Hemoglobin SS disease is a result of the homozygous expression of a mutant globin gene. (Valine replaces glutamic acid at the sixth position on the globin chain.) Deoxyhemoglobin S spontaneously polymerizes into fibers that cause the characteristic distortion and rigidity of the sickled cell. The vascular occlusion caused by these abnormal red cells accounts for many acute and chronic problems of SCA.

Retrospective analysis of autopsy data in 1973 suggested that the mortality rate, primarily due to overwhelming infection, was 20 to 30% in the first 5 years of life.[18] Survival beyond 40 years of age was uncommon. Today, better awareness of the disease and its potential complications have improved the outlook for affected persons.

Our study indicates that in mildly symptomatic adults with SCA, the LV function was normal or near normal at rest and during exercise, and that the LV perfusion pattern was also normal at rest. Thus, myocardial fibrosis secondary to coronary vaso-oclusive disease is not common. However, the LVEF was lower in patients with SCA than age-matched normal subjects both at rest and during exercise. Previous studies in patients at rest have also shown normal LV function.[19–21] In the study of Covitz et al,[21] the resting EF was <50% in only 2 of their 22 patients (9%), and an abnormal response to exercise was noted in 4 patients. In contrast, RV function was abnormal at rest and during exercise (or both) in most of our patients. RV function was abnormal in 7 of our 8 patients with clinically recognized RV dilation or a loud pulmonic component of the second heart sound.

Abnormal RV uptake of thallium-201 at rest suggests RV pressure or volume overload (or both).[22,23] Although RV volumes were not directly measured in our study, they must have increased, because the LV was dilated, the RVEF was lower than LVEF, and the stroke volume of both ventricles is the same in the absence of valvular regurgitation. LV dilation and high resting cardiac output seen in our study support previous findings.[7,11,12,19,20] Some possible reasons for RV dysfunction in our patients are pulmonary hypertension,

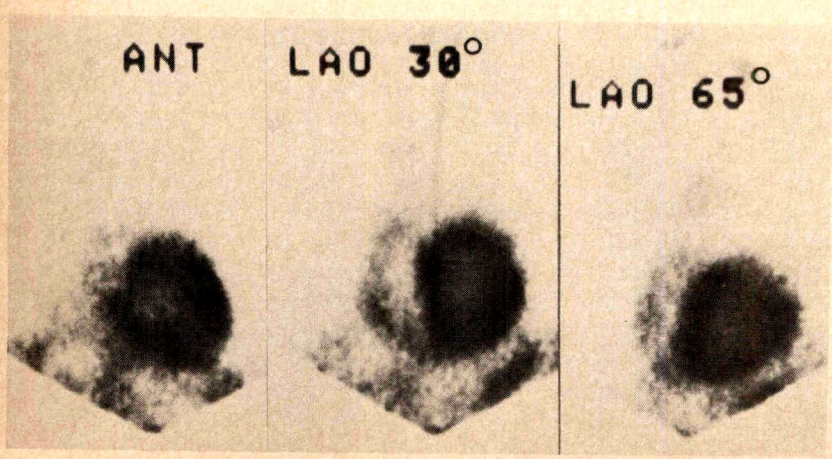

FIGURE 1. Resting thallium-201 image showing normal left ventricular perfusion and right ventricular uptake. ANT = anterior; LAO = left anterior oblique.

chronic volume overload, iron overload and coronary artery disease. None of the patients had evidence of coronary artery disease based on their age, history, exercise electrocardiographic response or exercise LV function. Whether chronic volume overload can produce isolated RV dysfunction is not known. A previous study[24] suggested that RV function was normal in patients with RV volume overload due to atrial septal defect. Pulmonary hypertension has been described in patients with SCA,[9,12] although it is unlikely to be due to LV dysfunction or chronic obstructive lung disease, since LV function was normal and there were no historical or clinical findings to suggest the diagnosis of chronic obstructive lung disease.

Thus, RV dysfunction in patients with SCA is most likely due to pulmonary hypertension secondary to repeated pulmonary infarctions. This finding is in agreement with the results of Korr et al,[24] who found a significant correlation between RVEF and pulmonary artery pressure. Confirmation of pulmonary hypertension by hemodynamic measurement would have been useful, but invasive studies in these patients were not justifiable. Considering the magnitude of the problem, the scarcity of exercise data, especially exercise ventricular function, is surprising. In our study and that of Covitz et al,[21] the exercise capacity was reduced despite the presence of a high cardiac output state, probably because of the decrease in the oxygen-carrying capacity of the blood.

The noninvasive nature of the radionuclide procedures used in this study offers a distinct advantage. Future investigators should consider the natural history of the disease relative ventricular function, especially with a view to ascertaining whether abnormal function can be detected and possibly corrected at an earlier stage of the disease.

Effects of Negative Pleural Pressure on Left Ventricular Hemodynamics

SHELDON A. MAGDER, MD, SAMUEL LICHTENSTEIN, MD, PhD, and ALLAN G. ADELMAN, MD

Negative pleural pressure alters left ventricular (LV) function. LV volume changes have been studied in human subjects, but little is known of the hemodynamic effects. The effect of changes of pleural pressure on LV hemodynamics during a Mueller maneuver (inspiration against an obstruction) was studied in 11 subjects and during quiet, unobstructed inspiration in 3. During the Mueller maneuver, there was an initial decrease in pulmonary wedge pressure and aortic systolic pressure, almost as great as the decrease in pleural pressure. Thereafter, these pressures increased despite a sustained reduction in pleural pressure. Toward the end of the Mueller maneuver, pulmonary wedge transmural pressure averaged 31 ± 12 mm Hg and in 6 patients large *v* waves developed. The increase in aortic transmural pressure averaged 30 ± 16 mm Hg. Aortic pulse pressure decreased on the first beat from control levels of 59 ± 21 to 47 ± 21 ($p < 0.001$) and then returned to control levels.

During normal breathing in 3 subjects, studied with intraesophageal balloons, there was a similar increase in both transmural aortic and transmural pulmonary wedge pressures with a decrease in pleural pressure 6 mm Hg during inspiration.

Thus, increased negative pleural pressure was associated with a marked increase in pulmonary wedge transmural pressure; the increase was approximately proportionate to the decrease in pleural pressure. It is suggested that this increase was due to increased impedance to LV ejection and to right ventricular expansion interfering with LV diastolic filling.

(Am J Cardiol 1983;52:588–593)

Fluid accumulation in the lungs is enhanced by very negative pleural pressures[1] and negative pleural pressures are frequently seen in conditions with airway obstruction[2] as well as conditions with noncompliant lungs such as pulmonary edema.[3] The potential mechanism for this fluid accumulation has become clearer in the past few years. Negative pleural pressure affects left ventricular (LV) function by at least 2 mechanisms: It causes an increase in the venous return to the right side of the heart,[4] which results in increased right ventricular (RV) volume, a shift in the ventricular septum to the left,[5] and RV interference with LV function.[6–11] It also produces an impedance to LV ejection.[9–15] Both of these mechanisms lead to an increase in left atrial LA transmural pressure (that is, LA pressure relative to pleural pressure). This increases the pulmonary venous and capillary hydrostatic pressures, which, in turn, leads to greater fluid accumulation in the lungs.[1,2] The effects of a negative pleural pressure on LV volumes has been well studied,[14,15] but few data are available on the ventricular pressure changes in human subjects.[16] This study quantitates the increase in LA and aortic transmural pressure during an inspiratory effort to determine the potential magnitude of the hemodynamic effects of negative pleural pressure in human subjects.

Methods

The effects of the Mueller maneuver were observed in 7 men and 4 women, aged 39 to 66 years, during routine cardiac catheterization. Seven patients had coronary artery disease, 3 valvular disease and 1 dilated cardiomyopathy. The details of their hemodynamic findings are given in Table I. LA pressure was estimated from pulmonary wedge pressure determined by an end-hole 7Fr catheter inserted percutaneously into the femoral vein and advanced to the pulmonary wedge position. The P_W was compared with the LV end-diastolic pressure determined by a retrograde arterial catheterization. Changes in mouth pressure were used to estimate changes in pleural pressure. In a Mueller maneuver, there is no air flow; therefore, changes in mouth pressure closely reflect changes in alveolar pressure, which in turn reflect changes in pleural pressure.[10] A pressure manometer allowed the patient to see the extent of the pressure change. All pressures were measured with Statham strain-gauge transducers placed 5 cm above the table level.

11	39	5	13	8	11–14	78	2/4	89	CAD: single vessel

AI = aortic insufficiency; AS = aortic stenosis; CAD = coronary artery disease; EDVI = left ventricular end-diastolic volume index (normal = <98); EF = ejection fraction; LV = left ventricular (grade 1 = normal, 4 = severe dysfunction); LVEDP = left ventricular end-diastolic pressure; MI = mitral insufficiency; mod = moderate; MS = mitral stenosis; obst. = obstruction; PAP = pulmonary artery pressure; RAP = right atrial pressure; W = wedge pressure (except Case 4 with transseptal left atrial pressure).

Mueller maneuvers were performed by having patients inspire from end expiration (functional residual capacity) against a closed airway. After a number of practice sessions, a fairly constant negative pressure could be maintained for 8 to 15 seconds. Care was taken to avoid sucking with the cheeks and closing of the glottis. Patients were also instructed to avoid contracting their abdominal muscles, for this can elevate intraabdominal pressure and increase venous return. To study the changes during spontaneous respiration, an intraesophageal balloon was inserted to the level of the heart and filled with 0.5 ml of air in 3 patients (Cases 1, 2, and 3). Variations in intraesophageal balloon pressure, wedge pressure and aortic pressure were then studied during Mueller and normal respiration in the supine position. Similar results were found during the Mueller maneuver whether mouth or esophageal pressures were used.

Mean pulmonary wedge pressure was obtained by graphically integrating the phasic pressure; arterial pressure was measured at peak systole. The change in intrapleural pressure (P_{Pl}) with each maneuver was assumed to equal the change in mouth or esophageal balloon pressure. It was subtracted from the change in wedge (P_W) and aortic pressure (P_{Ao}) to calculate the net change in the transmural pressures (P_W-P_{Pl} and P_{Ao}-P_{Pl}). Similarly, changes in intraesophageal pressure during respiration were used to calculate changes in net transmural wedge and aortic pressures. The values during the first beat, the middle and end of the Mueller maneuvers were compared with the resting values by a paired Student *t* test. For respiration, the changes in intrapleural, wedge and aortic pressures from peak inspiration to expiration from 14 to 35 respiratory cycles were analyzed. During systole, the LV transmural pressure is almost equal to the aortic transmural pressure; we assume for the purpose of this discussion that changes in one are equivalent to changes in the other. Thus, increase of aortic transmural pressure indicates increased impedence to LV ejection.

Results

A typical response to the Mueller maneuver with change in mouth pressure is shown in Figure 1 and a change in esophageal pressure in Figure 2. The average response of 11 subjects during control breathing and during early, middle, late and post-Mueller maneuvers are shown in Figure 3 and Table II. In all subjects there was an immediate decrease in the wedge and aortic pressures relative to atmospheric pressure. The wedge

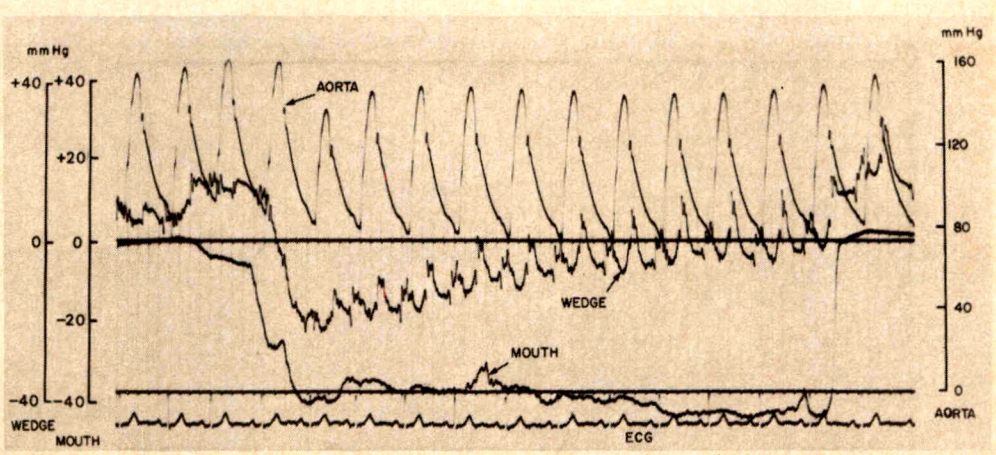

FIGURE 1. Aortic, (P_{Ao}) wedge (P_W) and mouth (P_M) pressures ($\Delta P_{pl} \simeq \Delta$ P mouth) during Mueller maneuver in Case 8. The **line in the center** is zero pressure for the mouth and wedge. With the abrupt decrease in P_M, the P_W decreased and then increased almost back to control levels. The P_{Ao} also decreased initially and then oscillated around the control pressure. Since the P_{Ao} and P_W did not decrease as much as P_M and increased further while P_M was constant, their transmural pressures increased considerably. Note the rebound in P_W on release of the Mueller maneuver. ECG = electrocardiogram.

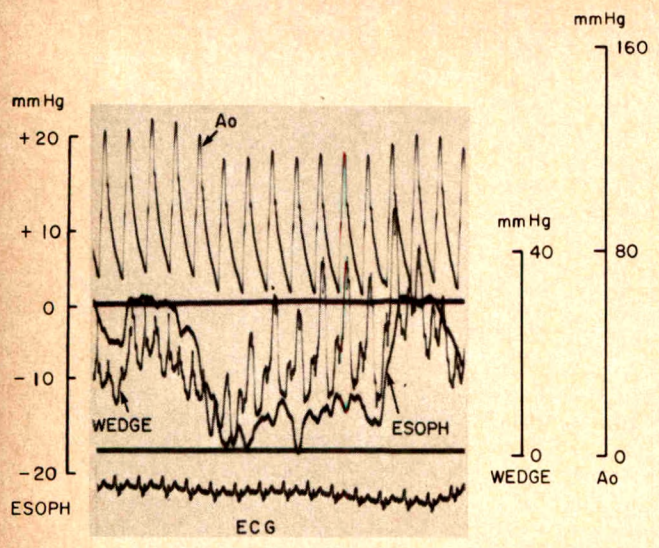

FIGURE 2. Aortic (Ao), wedge (WEDGE) and esophageal (ESOPH) pressures during Mueller maneuver in Case 3 demonstrating the development of large *v* waves.

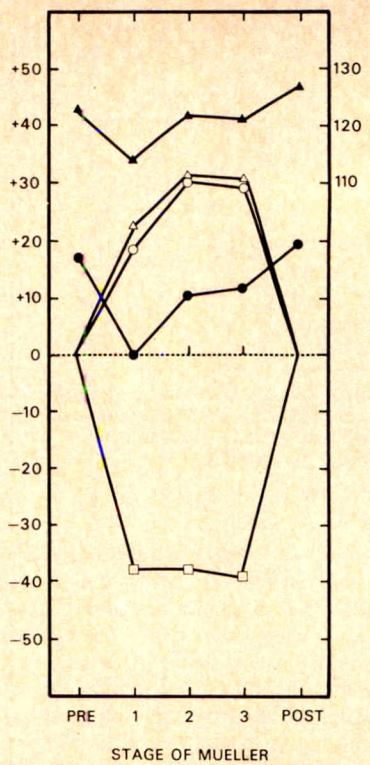

FIGURE 3. Mean changes in intraluminal mean left atrial, aortic (systolic) and transmural pressures (mm Hg) during Mueller maneuvers in 11 subjects. **Filled circles,** intraluminal left atrial pressure; **empty circles,** change in mean transmural left atrial pressure; **empty squares,** change in mouth pressure; **filled triangles,** intraluminal aortic systolic pressure; **empty triangles,** change in transmural aortic systolic pressure.

pressure then usually increased, but not back to the control level. The arterial pressure returned to near control levels or higher within 3 to 4 beats. With the onset of the Mueller maneuver, the decrease in pleural pressure was always greater than the decrease in wedge and aortic pressures, and therefore, the transmural pressures increased even on the first beat.

In Figure 4 the changes in LA transmural pressure as determined by pulmonary capillary wedge pressures are plotted against the changes in pleural pressure. Transmural pressure increased as a function of the decrease in pleural pressure and tended to be higher in the middle and late Mueller maneuvers than at the beginning of the maneuver. Only 2 patients at some point had no increase in transmural wedge pressure (Case 10, a woman with mitral stenosis and regurgitation and Case 4, a man with aortic regurgitation and stenosis).

The average changes in pulse pressure and RR interval during maneuvers are shown in Table II. Pulse pressure decreased immediately and then returned to control levels within 3 to 4 beats. There was an immediate shortening of the RR interval, with a return to control levels by the middle of the Mueller maneuver.

Large *v* waves developed in 6 subjects during the Mueller maneuver (Fig. 1 and 4). Two patients had valvular disease and small *v* waves at rest, whereas the other 4 had 3-vessel coronary artery disease and no mitral regurgitation on a subsequent left ventriculogram. The *v* waves tended to be more prominent during successive Mueller maneuvers.

* $p < 0.05$. † $p < 0.001$.
P_{Ao} = aortic pressure; P_{La} = left atrial pressures; P_{pl} = pleural pressure.

Figure 5 is an example of aortic wedge and intraesophageal balloon pressures during spontaneous respiration. The inspiratory decrease in intraesophageal pressure was greater than that in aortic and wedge pressures.

The relationship between P_{La}-P_{Pl} and P_{Ao}-P_{Pl} to P_{Pl} during inspiration are shown for Cases 1, 2 and 3 in Figure 6 and 7. While aortic and LA transmural pressures increased with increasingly negative pleural pressure, the increase was in each case somewhat less than the decrease in pleural pressure.

Discussion

As predicted, the decrease in pleural pressure with the Mueller maneuver and inspiration was associated with a decrease in LA pressures (as evident by pulmonary capillary wedge pressure) relative to the atmosphere, but an increase in LA transmural pressure, that is, LA intracavitary pressure minus pleural pressure. The overlying pericardium is considered to be a portion of the LA wall, and hence, LA transmural pressure re-

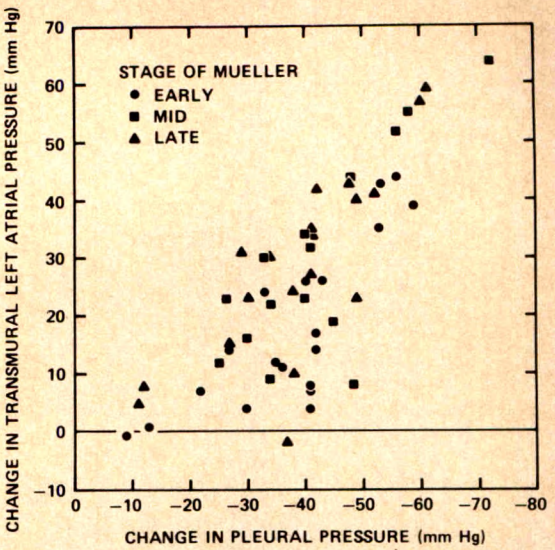

FIGURE 4. Changes in transmural left atrial pressure are plotted against changes in pleural pressure at 3 stages in the Mueller maneuver.

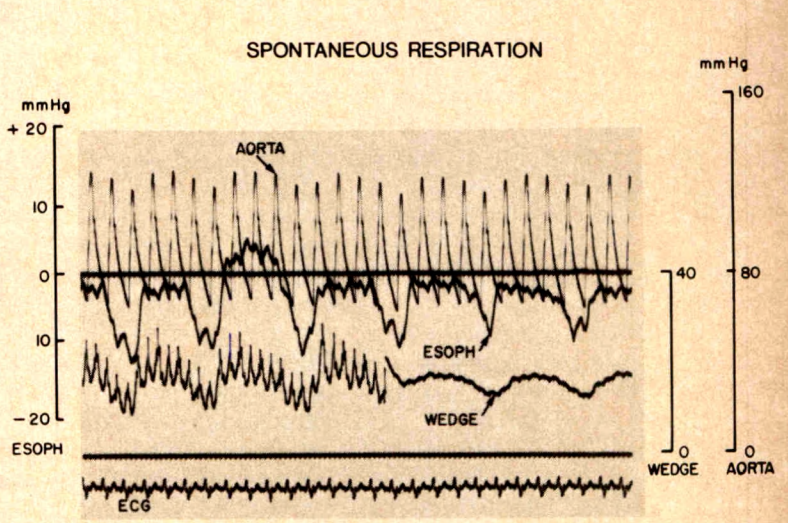

FIGURE 5. Aortic, wedge and esophageal pressures (pleural pressure) during normal respiration in the supine position for Case 1. Mean wedge pressure is also shown. Since the inspiratory decrease in pleural pressure was greater than the decrease in wedge and aortic pressure, the transmural aortic and left atrial pressures actually increased.

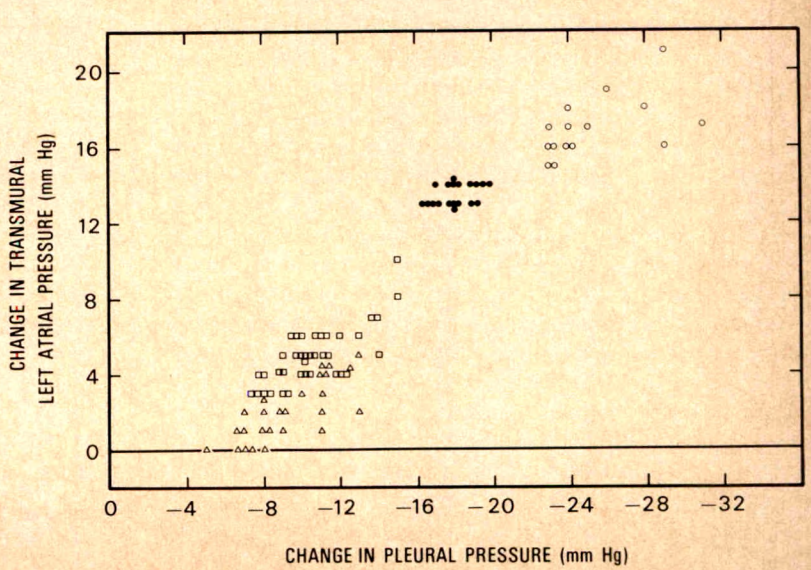

FIGURE 6. Changes in transmural left atrial pressure during inspiration in the supine posture are plotted against changes in pleural pressure for Cases 1 to 3. Patient 2 breathed with normal (**filled circles**) and deep inspiration (**empty circles**). **Triangles** represent Patient 1; **squares** represent Patient 3.

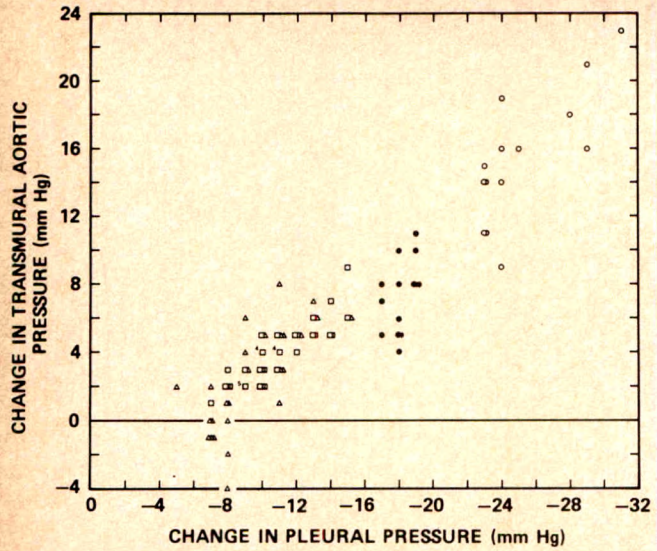

FIGURE 7. Changes in transmural aortic pressure during inspiration in the supine posture are plotted against changes in pleural pressure for Cases 1 to 3. Patient 2 breathed with normal (**filled circles**) and deep inspiration (**empty circles**).

flects the difference between pleural pressure and the LA cavity. With very negative pleural pressures, the LA transmural pressure increased to as high as 40 to 60 mm Hg. Thus, clinical conditions in which there are large swings in pleural pressure, such as tracheal obstruction or obstructive lung disease[2] or decreased lung compliance,[3] could cause large inspiratory increases in LA transmural pressure, which would in turn increase hydrostatic pressure at the pulmonary capillary level and potentially increase transudation of fluid.[1]

The dramatic rise in LA transmural pressure indicates that either the left-sided cardiac volume increased or the pressure-volume relation of the left heart shifted so that the same ventricular volume was associated with higher pressures.

The LV diastolic volume could be increased from the increase in LV afterload that develops with negative pleural pressure.[9–15] When pleural pressure decreases below atmospheric pressure, the left ventricle must overcome this negative pressure plus aortic pressure (during systolic ejection); thus, the left ventricle faces an increased afterload during ejection and end-diastolic volume will increase.[14] However, canine studies have shown that LA transmural pressure can increase during inspiration without an evident change in end-diastolic volume. One difference between the animal and human studies is that the negative pleural pressure was maintained constant in the human studies, and thus allowed time for volume adaptation to occur.[14] Furthermore, the heart is near its maximal volume in the supine position,[17] and therefore on the steep portion of its pressure volume curve; a small increase in ventricular volume could produce a large increase in transmural pressure. However, in addition to the increased afterload with negative pleural pressure, there is most likely a change in the pressure-volume relation of the left side of the heart from RV interference with LV function.[7–9] This change occurs because venous return to the right side of the heart increases with the decrease in pleural pressure and the increased RV volume thus increases RV interaction with the left side of the heart.[5–10]

Ventricular interaction cannot be the only explanation for the increase in LA transmural pressure for the pressure increased progressively during the Mueller maneuver, even though the pleural pressure did not change. It seems unlikely that the progressive increase in LA transmural pressure occurred because of a continuous increase in right heart volume. More likely, increased output from the right ventricle[18] reached the nearly maximally dilated left ventricle so that there was a large increase in LV diastolic pressure from a small increase in volume because the ventricle was on the steep portion of its pressure-volume curve.

The progressive increase in LA transmural pressure may also have been the result of a progressive increase in afterload, for after the first few beats the aortic pressure usually increased back to control levels despite sustained negative pleural pressure. Thus, there was further increase in LV afterload. As shown in Figure 3, the mean increase in LA pressure paralleled the mean increase in aortic transmural pressure.

The concept of transmural pressure applies when one is dealing with an elastic structure. When the heart is maximally dilated, it is effectively very stiff or inelastic. Thus, further decreases in pleural pressure will have little effect on the diastolic volumes, and the transmural pressure should increase in proportion to the decrease in pleural pressure. This was the case at the most negative pleural pressures (Fig. 3).

There was always a reduction in pulse pressure in the first few beats during the Mueller maneuver, which implies that stroke volume decreased, as is known to occur during inspiration.[18–20] Pulse pressure returned to normal by the midportion of the Mueller maneuver, suggesting either reflex changes in cardiac contractility or maintenance of output by higher end-diastolic volumes. The decrease in stroke volume is best explained by the RV interference with LV function[6–11] and by negative pleural pressure acting as an impedance to LV ejection[9–15] as discussed previously. The older belief that the inspiratory decrease in stroke volume is a result of pooling of blood in the lungs,[18,19,21] and thus decreased ventricular filling, is unlikely, considering the very large increase in LA transmural pressure[10,20] and the demonstration that end-diastolic volume does not decrease during inspiration.[13–15]

There are several possible explanations for the large *v* waves that developed during the Mueller maneuver. The increased LV afterload could have increased preexisting mitral regurgitation, which was known to be present in 2 subjects and increased LV volume might have caused mitral regurgitation in the others. The rapidity with which regurgitation developed and disappeared makes transient papillary muscle ischemia an unlikely cause. Alternatively, the large *v* waves could have been due to increased LA filling and not mitral regurgitation.

The decrease in pleural pressure with normal respiration produced a similar pattern of change in LA

transmural and aortic transmural pressures, as seen during the Mueller maneuver (Fig. 6 and 7). In addition to the mechanisms discussed, during normal inspiration lung inflation adds on impedance to RV ejection,[22,23] which would further increase RV volume on inspiration and exaggerate RV interference with LV function.

In the clinical setting, the relative role played by increased RV volume and increased LV afterload during negative pleural pressure varies with the circumstances. LV afterload is increased in direct proportion to the extent and duration of the decrease in pleural pressure during inspiration.[24] Because the decrease in stroke volume for any given increase in afterload varies with the status of the LV muscle, inspiratory impedance to LV emptying will cause greater reduction in stroke volume when LV function is depressed. The role of mechanical coupling will be greater when the venous pressure is elevated, because inspiration will cause a greater increase in venous return for any given decrease in pleural pressure. Similarly, pericardial effusion or rapid increase in heart size will tend to increase pericardial tension and also enhance the mechanical coupling between the right and left ventricles.

Acknowledgment: We thank Saul Permutt, MD, and Maurice McGregor, MD, for their help in preparing this manuscript.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal*. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

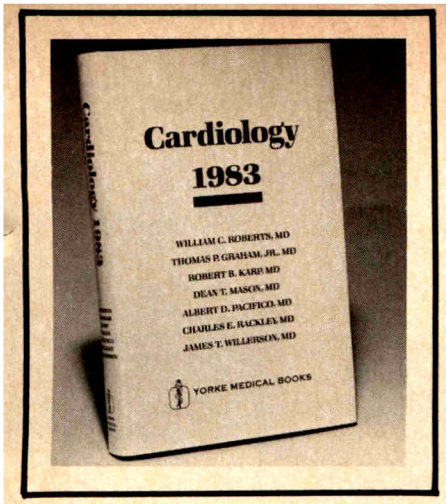
Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present, a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.



The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

Cardiology 1983

What is CARDIOLOGY 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

- **William C. Roberts, MD**
  Chief, Pathology Branch National Heart, Lung & Blood Institute National Institutes of Health Bethesda, Maryland, and Clinical Professor of Pathology and Medicine (Cardiology) Georgetown University, Washington, D.C.
- **Thomas P. Graham, Jr., MD**
  Professor of Pediatrics Chief, Division of Pediatric Cardiology Department of Pediatrics Vanderbilt University Vanderbilt Hospital Nashville, Tennessee
- **Robert B. Karp, MD**
  Professor of Surgery Department of Surgery University of Alabama Medical Center Birmingham, Alabama
- **Dean T. Mason, MD**
  Editor-in-Chief The American Heart Journal Director, Cardiac Center Cedars Medical Center Miami, Florida
- **Albert D. Pacifico, MD**
  Professor of Surgery Department of Surgery University of Alabama School of Medicine Birmingham, Alabama
- **Charles E. Rackley, MD**
  Professor and Chairman Department of Medicine Georgetown University Medical Center Washington, D.C.
- **James T. Willerson, MD**
  Professor of Medicine Chief, Division of Cardiology Department of Medicine University of Texas Health Science Center Dallas, Texas

Reviews of previous editions

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, MD
JAMA, November, 1981

"...It is more than merely a reference book, since it explains what to the average physician may be obscure...a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, MD
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

"Dr. Roberts and his colleagues have done it again...All in all, this is a remarkable tour de force of inestimable value to all physicians struggling to understand the heart and its problems."
David H. Spodick, MD
Practical Cardiology

ISBN 0-914316-36-2 approx. 500 pp., illus., Summer '83 $49.50

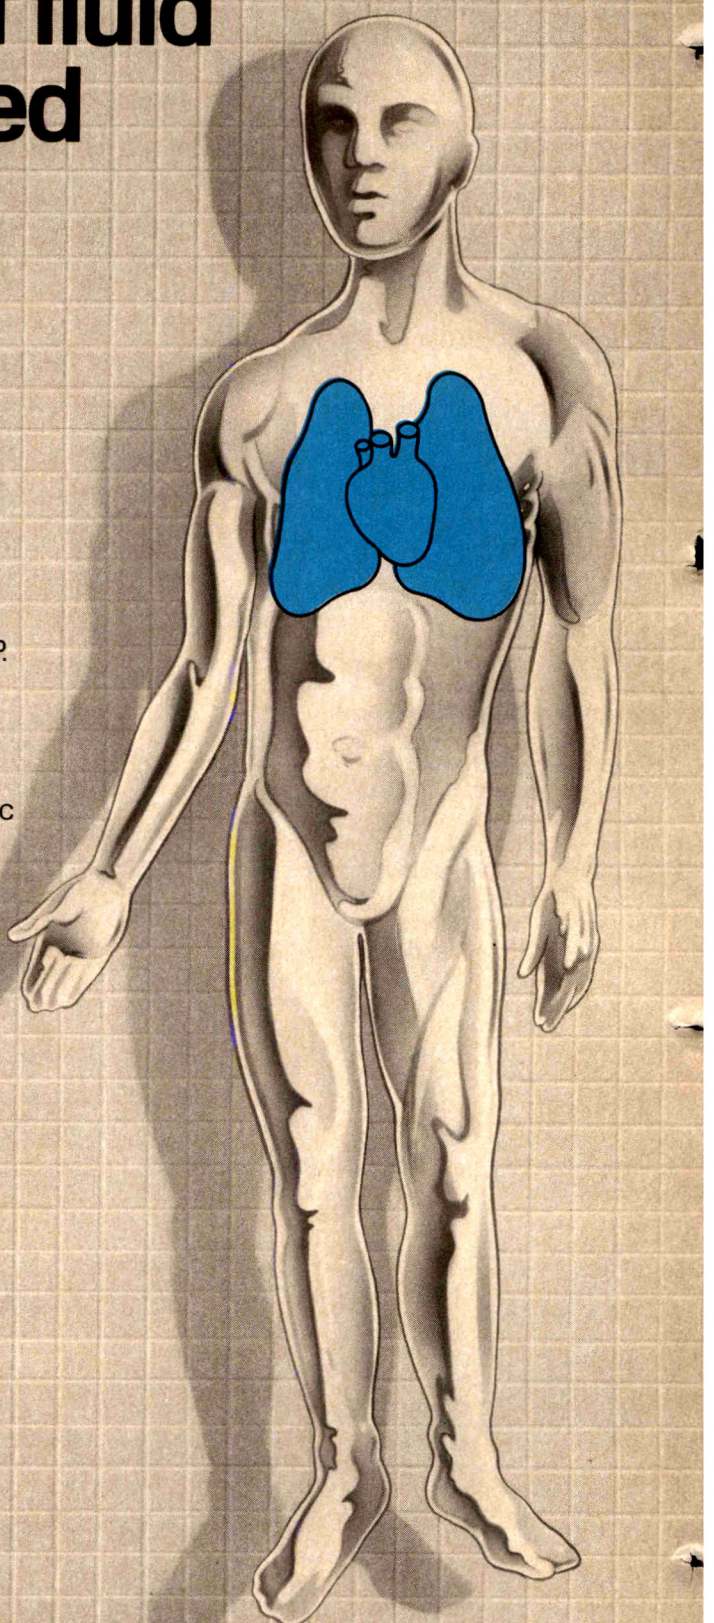
Therapeutic challenge:

Redistribution of fluid in CHF associated with acute MI



In Early CHF[1]

Pulmonary congestion with increased preload.

Findings: Elevated preload, elevated blood pressure, normal or slightly decreased cardiac output; PCWP greater than or equal to 18 mm Hg.

Therapeutic goal:
Reduce pulmonary congestion, lower PCWP to 15 to 18 mm Hg.

In Late CHF[1]

Pulmonary congestion with increased preload and afterload.

Findings: Low cardiac output, depressed blood pressure, and high PCWP.

Therapeutic goal:
Reduce pulmonary congestion, preload, and afterload, increase cardiac output, and lower PCWP to 15 to 18 mm Hg.

Why wait for the patient to become unresponsive to traditional diuretic/digitalis therapy?

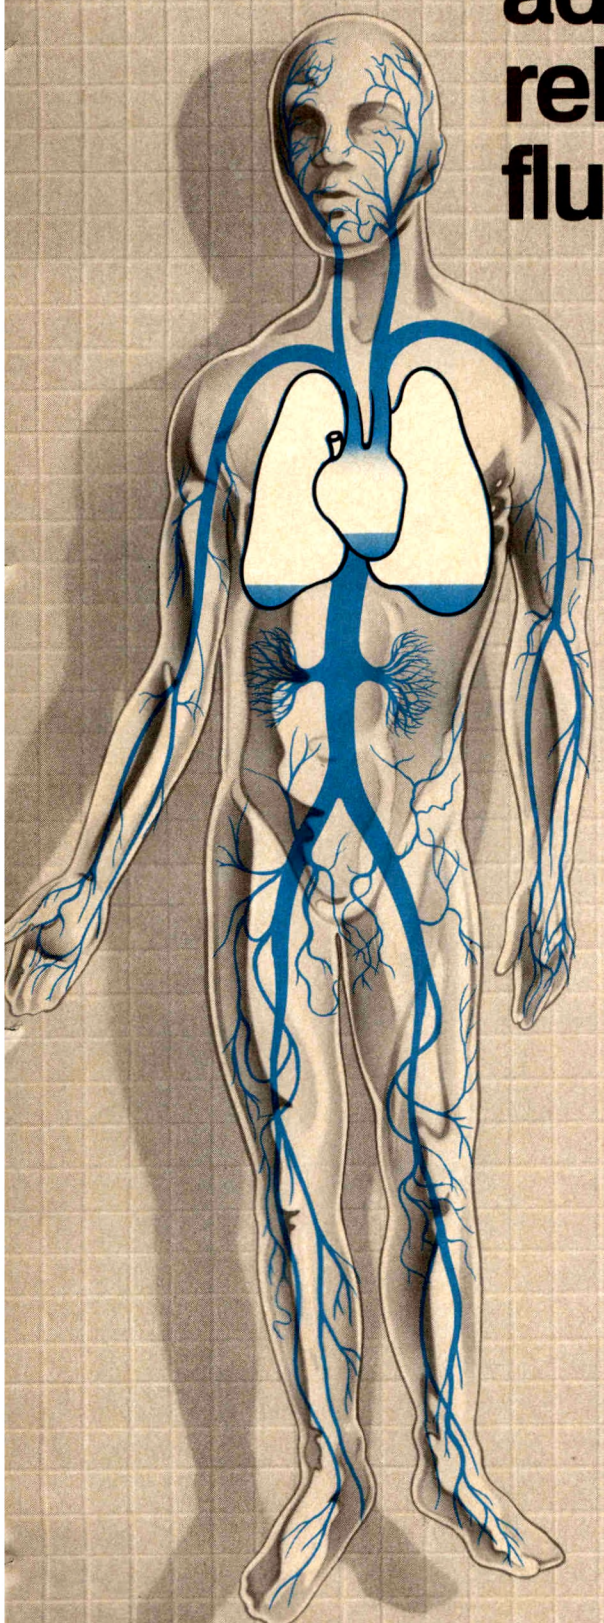
Division of American Hospital Supply Corporation

Give Tridil® (nitroglycerin) adjunctively to help relieve the fluid-burdened heart



In a dose-related manner, Tridil produces dilation of both arterial and venous beds—for a therapeutic redistribution of fluid.

Suggested therapy in early CHF

If blood pressure is normal:
Tridil to reduce preload and PCWP. Diuretics to decrease fluid volume.

If blood pressure is elevated:
Tridil should be initiated immediately to decrease preload, PCWP, and blood pressure, while maintaining coronary perfusion.

Suggested therapy in late CHF

If blood pressure is normal or only moderately depressed:
Vasopressors and Tridil adjunctively, with continuous hemodynamic monitoring.

If blood pressure is significantly depressed:
Vasopressors and Tridil adjunctively to reduce preload, afterload, and PCWP. Dopamine to increase the contractility of the myocardium. PCWP should be monitored.

Use of nonabsorbing Tridilset®

Sorptive loss of Tridil may range up to 80% when infused through a conventional PVC administration set[2] To overcome this problem, administer Tridil through Tridilset administration set or Tridilset V.I.P.™ volumetric pump connector set.

The most frequent adverse reaction in patients treated with Tridil is headache. Please see the following page for a brief summary of prescribing information. Note: Tridil is a potent drug and must be diluted before infusion.

For additional information, contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinyl chloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,® an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-05, 25 mg-5 ml ampul. NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

ATLAS OF CARDIAC SURGERY

DAVID H. DILLARD, M.D., D.Sc.(Hon.), F.A.C.S., and DONALD W. MILLER Jr., M.D., F.A.C.S., both, University of Washington

Here, in one volume, is the current state of art in cardiac surgery. This authoritative atlas provides 115 full-page illustrations, with text on facing pages, of surgical procedures for cardiac operations of both acquired and congenital conditions. Surgical anatomy of the heart, pre- and postoperative care, the workings of the heart-lung machine, implantation of pacemakers, and the entire spectrum of cardiac operations are explained in step-by-step detail.

ECHOCARDIOGRAPHIC DIAGNOSIS

Differential Diagnosis of M-Mode and Two-Dimensional Echographic Appearances

IVAN A. D'CRUZ, M.D., F.A.C.C., F.R.C.P. (Edin.), M.R.C.P. (London), Michael Reese Hospital and Medical Center, and University of Chicago Pritzker School of Medicine

Bridging the gap between textbook knowledge and practical diagnostic expertise, this book provides extensive help in the everyday interpretation of echocardiograms. The presentation enables the clinician to become familiar with a wide variety of M-mode and 2-D echocardiographic patterns—common and uncommon—in terms of their clinicopathologic implications, and to distinguish echographic patterns that are similar but etiologically diverse. Line drawings render explicit the abnormalities in many of the echocardiographic reproductions, and the author offers invaluable advice on obtaining reliable tracings.

Forthcoming

ANGIOCARDIOGRAPHY OF CONGENITAL HEART DISEASE

ROBERT M. FREEDOM, M.D., F.R.C.P.(C), F.A.C.C., The University of Toronto, and The Hospital for Sick Children, Toronto; J.A.G. CULHAM, M.D., F.R.C.P.(C), University of British Columbia, and British Columbia's Children's Hospital, Vancouver; and C.A.F. MOES, M.D., The University of Toronto, and The Hospital for Sick Children, Toronto

This comprehensive volume provides an indepth look at the angiocardiography of congenital heart disease, and also includes some pathologic considerations. The hundreds of high-quality angiocardiograms, the well-organized text, and the thousands of up-to-date references give pediatric cardiologists, cardiac surgeons, cardiac radiologists, and others invaluable information on anatomic combinations and clinical data.

CARDIOVASCULAR REHABILITATION

A Comprehensive Approach

Edited by LYSLE H. PETERSON, M.D., The Houston Cardiovascular Rehabilitation Center, and University of Texas Health Science Center, Houston

This multicontributor book is written for the busy physician who wishes to know how a properly conducted comprehensive cardiovascular rehabilitation center can be of major benefit to the patient. A clear demonstration of the philosophy, scope, and practical clinical aspects of successful cardiac rehabilitation is evident throughout the 16 chapters concerning exercise and exercise tolerance testing, ergometry, psychological disorders, nutritional management, coronary artery disease, cardiovascular nuclear medicine, insurance/risk evaluation, and health care costs.

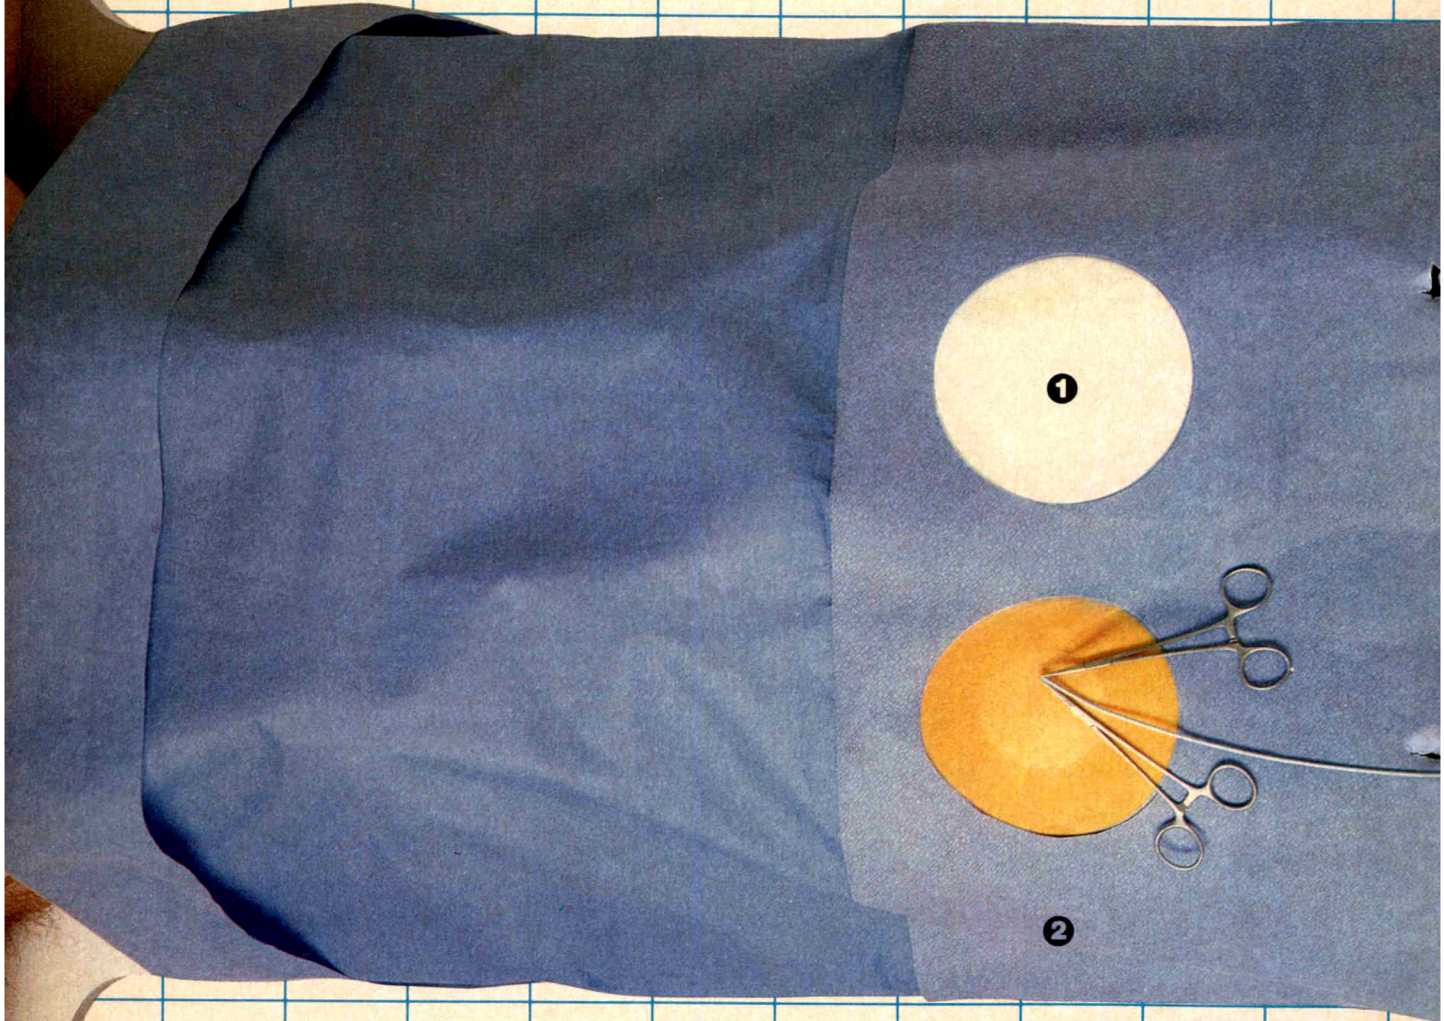
American Convertors New Angiography Drape

A Clear Advantage

❶ Larger Outer Fenestration

Larger visible field gives you a better view of the operative site.

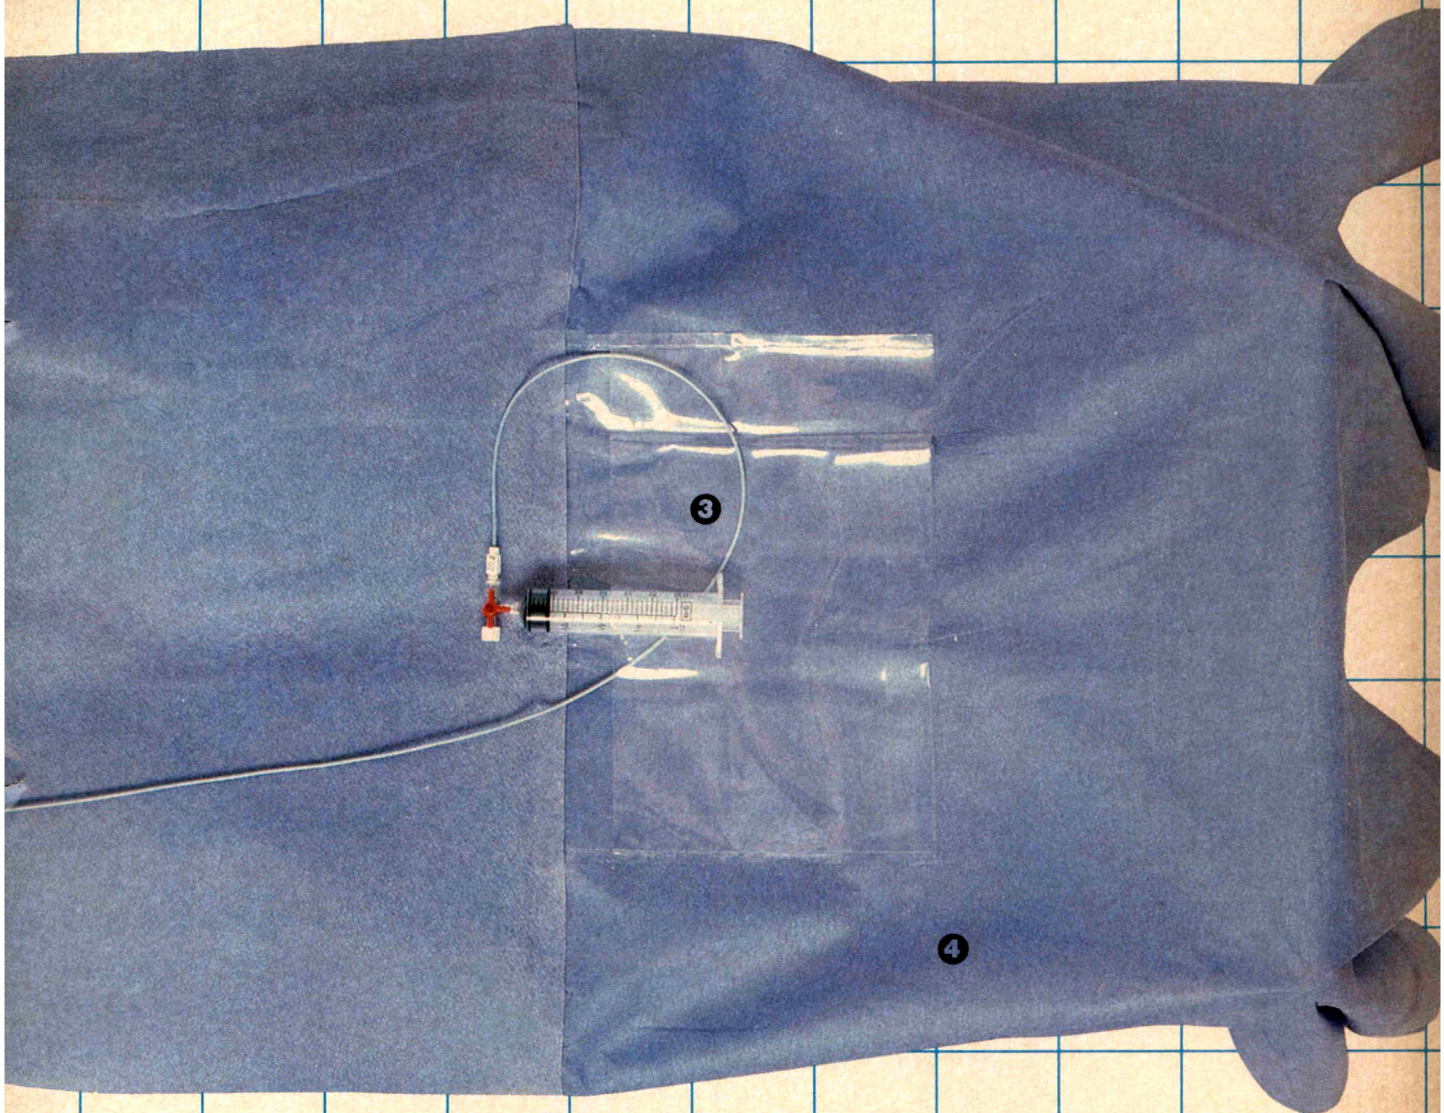


❷ Increased Patient Protection

Iso•Bac™ antimicrobial fabric serves as an absorbent reinforcement to provide safe fluid control and prevent fluid strikethrough.

3 Catheter Pouch

American Convertors offers the only angiography drape with catheter pouch for increased control.



4 New Shield® Fabric

Soft, fluid repellent Shield fabric drapes naturally for maximum control and patient comfort.

For more information, contact American Convertors, Division of American Hospital Supply Corporation, 1740 Ridge Avenue, Evanston, IL 60201, 312/866-4600.

Writing with care for CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF (furosemide)

9 out of 10 cardiologists specify LASIX® (furosemide) by brand name.* And 2 out of 3 take the extra step to prevent substitution.*

7 out of 10 cardiologists also specify the leading brand of digoxin.* Both are part of the classic LASIX®-digitalis regimen.

In the same survey,* LASIX® and the leading brand of digoxin were named more often than any other agent, in any therapeutic class, as drugs for which these cardiologists would *never* allow generic substitution. Both were prescribed by brand name more often than any other drug.

LASIX®—specified for good reason.

Especially in CHF, precision is crucial. Any therapeutic variable could easily upset the sensitive digitalis/diuretic/electrolyte balance and precipitate digitalis toxicity.

LASIX®, the most thoroughly documented drug in its class, offers quality so consistent that almost 8 billion tablets have been manufactured without a single product recall. In more dosage strengths and forms than any other diuretic. Good reason for the cardiologists surveyed to say they prescribe LASIX® more frequently than all other diuretic agents they named.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

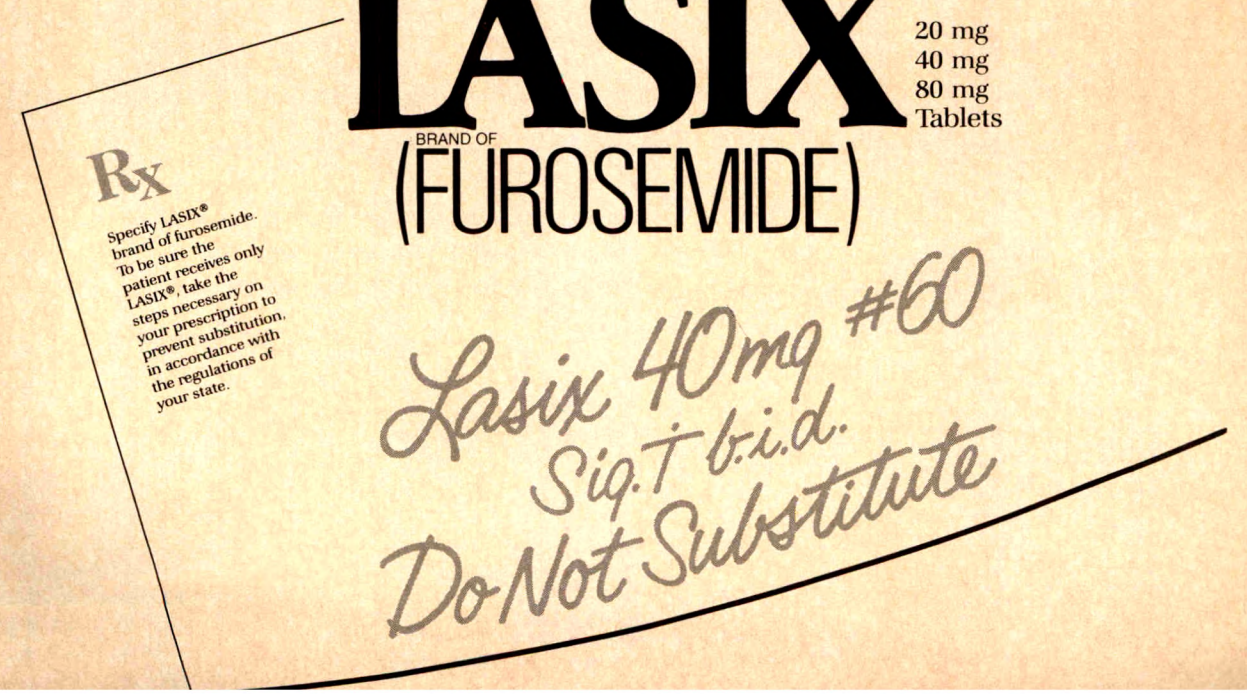
*National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August, 1982.

The diuretic of choice in CHF.

LASIX®

20 mg
40 mg
80 mg
Tablets

BRAND OF (FUROSEMIDE)



Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions.

Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion: this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

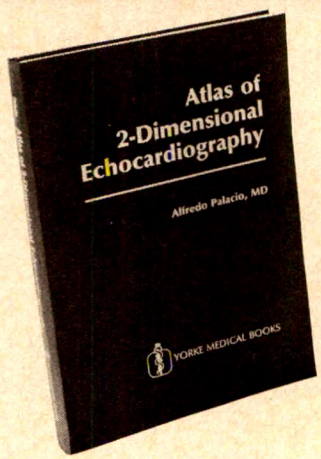
The First Practical Atlas of 2-D Echocardiography Ever Published



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

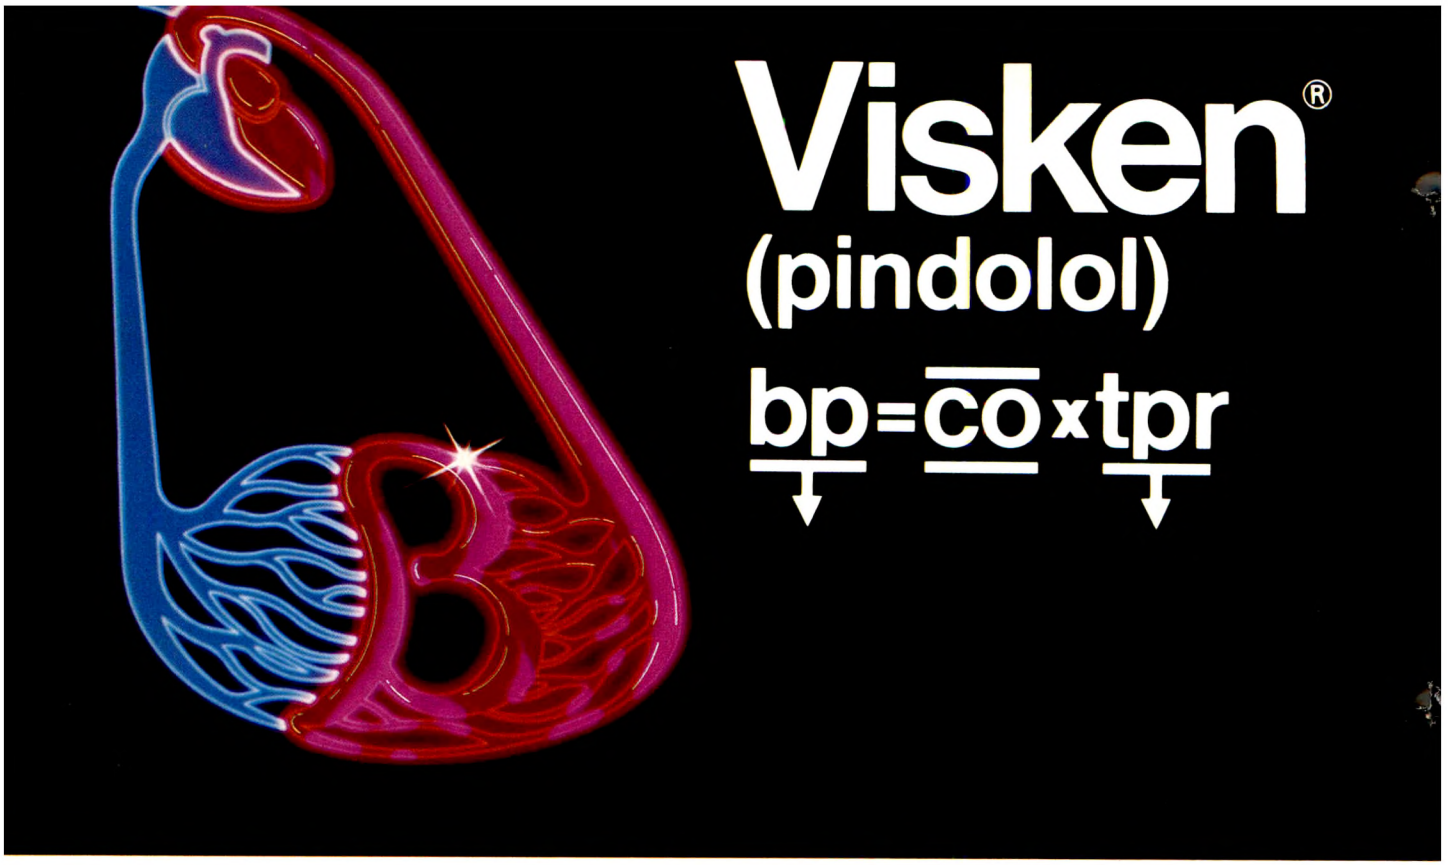
The
Visken® (pindolol
difference
All other
beta blockers
bp=co×tpr
Visken (pindolol)
bp=co×tpr



Makes hemodynamic sense in the treatment of hypertension

Reduces blood pressure

It's as effective as propranolol in normalizing blood pressure (dbp ≤ 90 mmHg) when used alone. It's also effective when used in combination with a diuretic.[1]

Has little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) maintains resting cardiac output during long-term therapy. The clinical significance of this has not been evaluated.

Reduces total peripheral resistance*

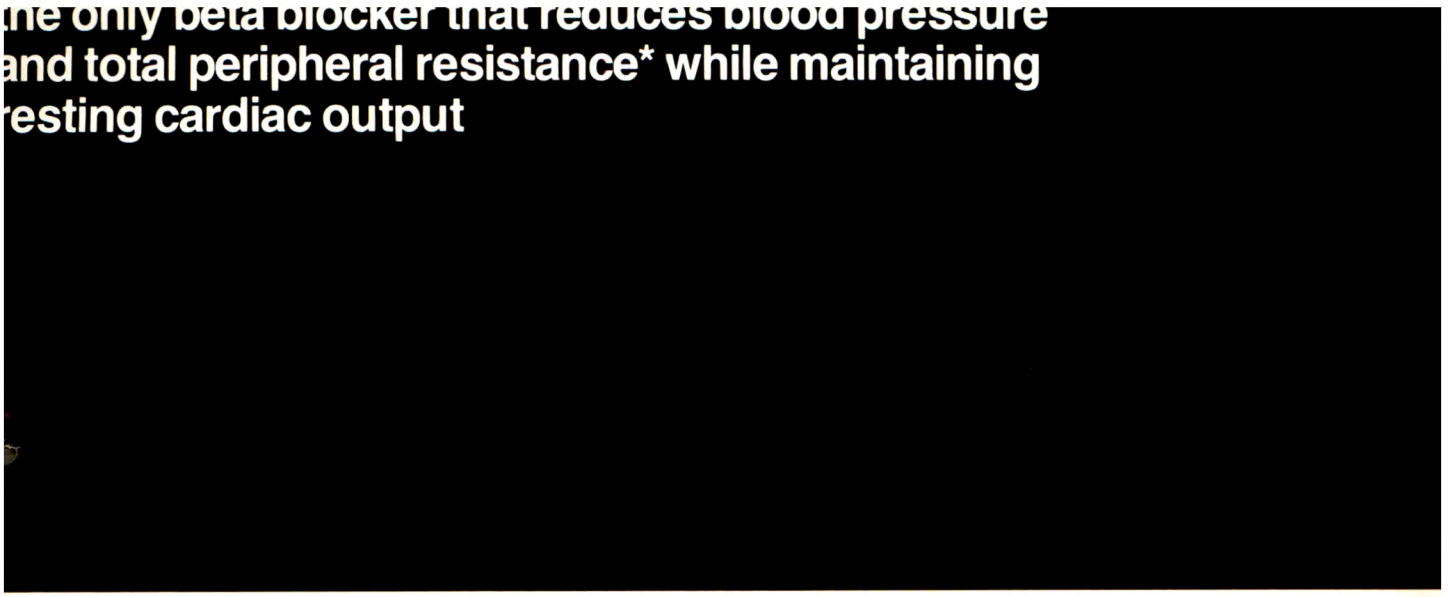
Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.* Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

Reduces exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

© 1983 Sandoz, Inc.

*The clinical significance has not been evaluated. See clinical significance statement on facing page of this advertisement.



Has little effect on resting heart rate

Visken® (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute.

The clinical significance has not been evaluated

The clinical significance of maintaining resting cardiac output, resting heart rate and reduced total peripheral resistance has not been evaluated and there is no evidence or reason to believe that exercise cardiac output is less affected by Visken (pindolol) than other beta blockers.

Maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

Favorable side effect profile

Low incidence of bradycardia

Low incidence of cold extremities

Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

*See clinical significance statement.

Please see next page of this advertisement for brief summary of prescribing information.

Visken® (pindolol)

The recommended initial dose of Visken (pindolol) is 5 mg b.i.d.

Many patients respond to 10 to 30 mg a day. The maximum dose is 60 mg per day. Dosage should be titrated on an individual basis. Available in 5 mg and 10 mg tablets.

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

Body System/ Adverse Reaction	Total (Volunteered and Elicited) Visken (pindolol) (N = 322) %	Active Controls* (N = 188) %	Placebo (N = 78) %
Central Nervous System			
Anxiety	4	<1	1

Skin			
Pruritus	2	<1	0
Rash	2	3	3

*Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointestinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

VIS-783-3

Effects of Posture and Respiration on Body Surface Electrocardiogram

DAVID J. SUTHERLAND, BSc, DAVID D. McPHERSON, MD,
C. ANNE SPENCER, BSc, C. SUSAN ARMSTRONG, MSc,
B. MILAN HORACEK, PhD, and TERRENCE J. MONTAGUE, MD,
With the technical assistance of SHARON A. BLACK, RN, *and* SUSAN M. RIGBY, RN

To define more fully the effects of posture and respiration on electrocardiographic (ECG) patterns, 120-lead body surface potential maps (BSPM) were recorded in 36 normal subjects (aged 21 to 48 years) during cyclic respiration in both supine and upright positions; and at static end-tidal inspiration, functional residual capacity (FRC), total lung capacity (TLC) and residual volume (RV). In addition, BSPMs were recorded at TLC and RV during the Valsalva and Müller maneuvers, respectively. P-wave, QRS and ST-segment time integrals were evaluated. From supine to upright position, there was an inferior torso shift of P-wave and QRS distributions, but no change in amplitude of their maximal or minimal values; ST-segment distributions were spatially unaltered, but there was a significant ($p < 0.01$) decrease in the maximal value. Relative to maps during cyclic respiration in the upright position, maps at end-tidal respiration were similar; maps at TLC, however, displayed an inferior displacement of P-wave and QRS distributions and a decrease of QRS maximal and minimal values ($p < 0.01$). Valsalva and Müller maneuvers were not associated with marked changes in the appearances of BSPMs. The magnitude of variability, as assessed by a root-mean-square index, was greatest between maps recorded at TLC and RV; the least variability occurred between maps recorded at end-tidal inspiration and FRC. The variability between maps recorded in the supine and upright positions was intermediate. When root-mean-square variability data of all interventions were normalized by dividing by the respective mean data range (maximum minus minimum) of each time integral, the variability of P wave > ST segment > QRS ($p < 0.01$).

Thus, resting tidal volume respiration has little effect on body surface ECG patterns in normal adults. However, large volume respiration and posture change may substantially alter ECG body surface distributions and should be considered in states involving either factor.

(Am J Cardiol 1983;52:595–600)

Because it can reflect most of the surface-available electrocardiographic (ECG) data, body surface potential mapping (BSPM) is a useful and increasingly used electrocardiographic technique.[1–10] The surface distributions and temporal variability of several ECG time integrals at supine rest during tidal volume respiration in normal adults[5] and the influence of respiration on QRS potentials in normal children[11] have been described. Comprehensive descriptions of the effects of posture change and respiration on various BSPM values have not, however, been heretofore available. These data are necessary to allow optimal analysis of the body surface ECG, particularly during dynamic physiologic states involving either posture or respiratory changes in association with other interventions. Consequently, this study was undertaken to provide a spatial and quantitative perspective of posture and respiration-associated effects on BSPM distributions.

Methods

Patients: Fifty-one persons, 27 men and 24 women aged 21 to 49 years, were studied. All subjects had a normal cardiac history, physical examination, time-motion echocardiogram and 12-lead electrocardiogram. None were taking cardiac medications.

Data recording and processing: The system of recording the body surface ECG signals has previously been described.[4,5,10] Briefly, simultaneous 15-second ECG recordings were obtained from 117 torso and 3 limb electrode sites with Wilson's central terminal as reference (Fig. 1). Data were recorded in digital format with a sampling frequency of 500 samples/s/channel. Computer-based analysis rejected ectopic beats and artifacts and performed selective averaging of the ECG complexes from each lead. For this study, the averaged complexes were placed on a baseline determined with a straight line from P onset to T offset, that is, a P-T baseline. Off-line editing of the 120-lead averaged analog display assessed P-QRS-T wave form, baseline placement and noise. Isolated individual leads judged unacceptable on initial editing were interpolated from surrounding lead site values. If >20 isolated or several clustered leads were judged unacceptable, the map was discarded from further analysis.

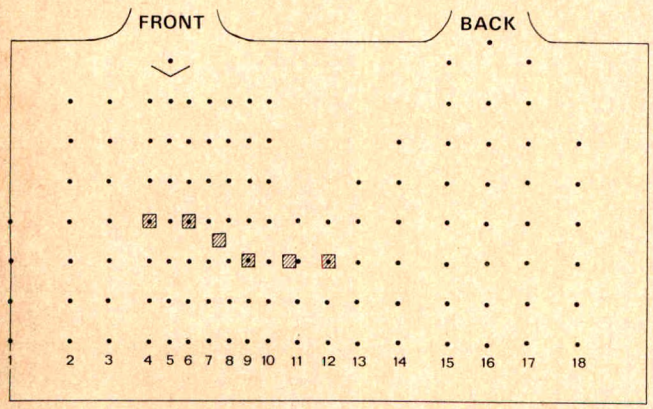

FIGURE 1. Electrode sites on the torso. The electrodes were mounted 5 cm apart, with the fourth electrode from the bottom of each strip positioned at the horizontal level of the fourth intercostal space, parasternally. The columns were placed vertically according to previously described anatomic landmarks.[5] Briefly, column 5 was placed over the sternum and column 16 over the spine. The standard V_1 to V_6 chest leads are illustrated (for reference purposes) by small **squares.**

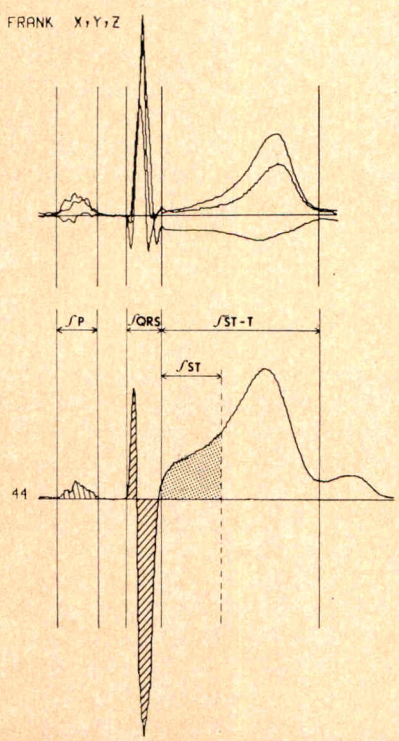

FIGURE 2. Top panel, the superimposed Frank X, Y and Z leads of a normal subject. **Vertical lines,** computer-identified time instants utilized for the various ECG time-integral measurements at each lead site. **Bottom panel,** the signal from a precordial lead of the same subject. P-wave, QRS and ST-segment time integrals are outlined by the **diagonal lines and stippling.** See text (Data Processing) for details.

Analysis of BSPM data was performed by previously described techniques.[5,10] For the purpose of this study, we focused on time-integral values of the P wave, QRS and ST segment, calculated for the averaged complexes at each torso lead site with use of time instants identified from simultaneously constructed Frank X, Y and Z leads (Fig. 2). The P-wave integral represented the algebraic sum of all potentials between the time instants of P onset and P offset multiplied by the sampling interval (that is, the net area under the P wave). The QRS integral was similarly calculated from QRS onset to QRS offset, and the ST-segment integral from QRS offset to the end of the three-eighths portion of the ST-T segment. The time-integral values were expressed as μV·s.

The data were displayed as isointegral contour maps. In this display mode, each rectangular area represents the torso surface with both vertical edges being the right midaxillary line; the left and right sides of the rectangle represent the front and back of the torso, respectively. Each contour line connects points of equal time-integral value. In individual and group-mean maps, the near-zero zone lies between areas of positive (solid contour lines) and negative (interrupted lines) time-integral values. There is a logarithmic progression of the isointegral lines away from this near-zero zone toward the numerically identified maximal and minimal values. In area-of-difference maps, constructed by subtracting the time-integral values of all lead sites in one map from the corresponding values in another, the results were also plotted in isointegral format. However, in these subtraction maps the solid lines represent torso areas where time-integral values were relatively greater in one map than in the other map; negative zones represent areas where the time-integral values of one map were relatively less than those of the other map.

Study protocol: Each subject had 8 sequential BSPM recordings. The first 2 maps were recorded during cyclic tidal respiration, 1 in the supine and 1 in the upright position. Subsequent maps were all recorded in the upright position, and with respiration arrested at end-tidal inspiration, functional residual capacity (FRC), total lung capacity (TLC), residual volume (RV), and TLC with the addition of the Valsalva maneuver, and RV with addition of the Müller maneuver. All 8 recordings for each subject were obtained within 30 minutes, and with the same electrode application. Mean P-wave, QRS and ST-segment maps were constructed for the study group at each intervention using the group-mean values at each lead site. Mean area-of-difference maps were also constructed for P-wave, QRS and ST-segment time integrals to delineate the difference in spatial distributions between supine and upright; end-tidal inspiration and FRC, TLC and RV, TLC and Valsalva, and RV and Müller maneuver.

Intermap variability in time-integral values was also assessed by deriving a root-mean-square index of variability according to the formula[5]

$$\text{Root mean square variability} = \sqrt{\frac{\Sigma_1^N (X_{T_2} - X_{T_1})^2}{N}}$$

where N is the number of lead sites, X the time-integral values at a particular lead site and T_1 and T_2 any 2 map acquisition times.[5] In addition, P-wave, QRS and ST-segment root-mean-square variability were normalized by expressing the

mean index of variability for all interventions (compared with values in the upright position) as a percent of the mean data range of each time integral. The data range for each time integral was defined as the absolute difference between the respective P-wave, QRS and ST-segment group-mean maximal and minimal values in the upright position.[5]

Statistical analysis: Two-way analysis of variance was used to test the null hypotheses that there were no differences between index of variability values, or maximal and minimal values, for P-wave, QRS and ST-segment time integrals. If a null hypothesis was rejected, Tukey's multiple comparison test was then used to determine which values were significantly different.

Results

After stringent editing of the recorded data, 36 subjects (23 men and 13 women, aged 21 to 48 years) had sufficiently high quality recordings at all 8 states for further analysis. All results were determined from these 36 subjects.

The group-mean P-wave, QRS and ST-segment isointegral maps for each of the study interventions are displayed in Figure 3. With position change from supine to upright, there was a downward spatial shift of P-wave and QRS time-integral torso distributions, but no sig-

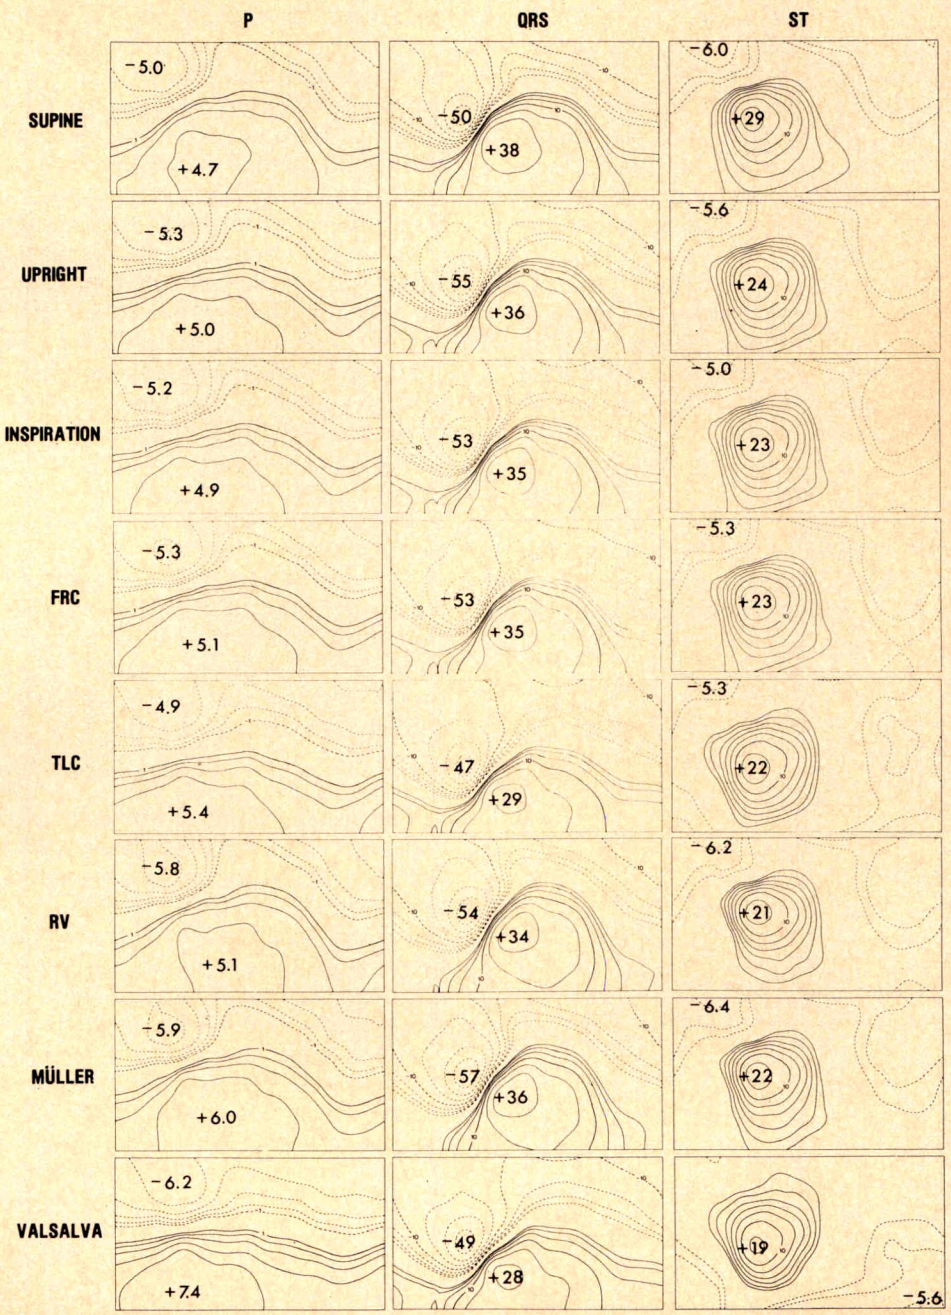

FIGURE 3. Mean P-wave, QRS and ST-segment isointegral body surface maps of 36 normal adult subjects during sequential interventions of position change and respiration. Each **rectangle** represents the torso unrolled: the **left half** reflects the anterior torso; the **right half** the back. The **contour lines** join points of equal value. The maximal and minimal values are numerically identified. FRC = functional residual capacity; RV = residual volume; TLC = total lung capacity.

nificant change in the amplitude of P-wave or QRS maximums and minimums. ST-segment integral distributions were spatially similar in both positions. However, the ST-segment maximum significantly decreased in amplitude (29 ± 13 [± standard deviation] μV·s, supine versus 24 ± 13 μV·s, upright; $p < 0.01$). Compared with maps recorded during cyclic tidal respiration (that is, in the upright position), maps recorded with arrested respiration at end-tidal inspiration and FRC showed no apparent spatial changes in P-wave, QRS or ST-segment distributions, nor any significant changes in amplitudes of maximums and minimums. Maps recorded at TLC showed a downward torso displacement of P-wave and QRS distributions and a significant decrease in the amplitude of QRS maximum (36 ± 19 μV·s, upright versus 29 ± 17 μV·s, TLC; $p < 0.01$) and an increase in QRS minimum (−55 ± 24 μV·s, upright versus −47 ± 23 μV·s, TLC; $p < 0.01$). ST-segment spatial distributions and maximal and minimal values were unchanged at TLC, relative to values in the upright position. At RV, there was an upward spatial displacement of the P-wave and QRS distributions but no change in ST distribution or maximal and minimal values compared with those in upright maps. Maps recorded with the Valsalva maneuver showed spatial P-wave, QRS and ST-segment distributions similar to those recorded at TLC, and a similar decrease in QRS maximums, compared with distributions in the upright maps. In addition, maps recorded during the Valsalva maneuver had a significant increase in the P-wave maximum and decrease in ST-segment maximum. In an analogous fashion, maps recorded during the Müller manuever were similar in spatial distribution to maps recorded at RV, both representing an opposite, upward torso shift in P-wave and QRS distributions relative to maps recorded at TLC and with the Valsalva maneuver.

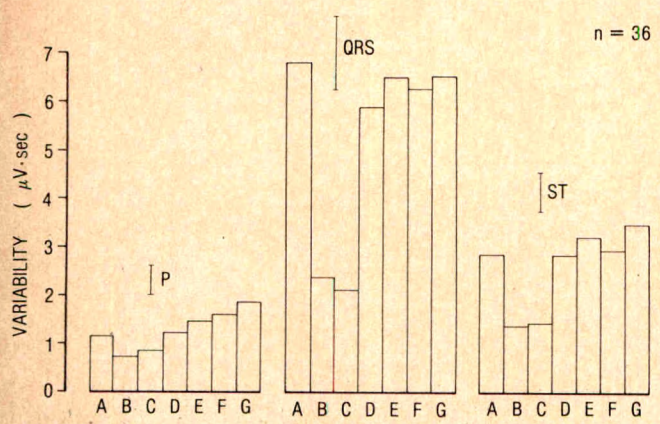

FIGURE 4. Group-mean root-mean-square variability of P-wave, QRS and ST-segment time-integral values at the body position and respiration intervention points, compared with cyclic tidal respiration in the upright position. The **letters** under each column identify the various interventions: The **bar** over each integral indicates the difference required to reach a significance level of $p < 0.05$ between any 2 interventions. A = supine; B = end-tidal inspiration; C = functional residual capacity; D = total lung capacity; E = residual volume; F = Müller maneuver; G = Valsalva maneuver.

The average root-mean-square variability between upright maps and each of the other states is illustrated in Figure 4. For each integral, maps recorded at the end points of tidal respiration (end-tidal inspiration and FRC) showed the least variability; maps recorded in the supine position and at maximal respiration points (TLC, RV, Müller and Valsalva maneuvers) showed the greatest variability.

The relative effects of position change, tidal respiration, maximal respiration, and Valsalva and Müller maneuvers on P-wave, QRS and ST-segment isointegral distributions are illustrated by the area-of-difference maps in Figure 5. As might be expected from consideration of the group-mean maps (Fig. 3) and the relative indexes of variability (Fig. 4), tidal volume respiration resulted in very small areas of difference for P-wave, QRS and ST-segment distributions. Position change and maximal respiratory volume change resulted in much greater areas of difference for all time integrals. However, the addition of the Valsalva maneuver to TLC and the addition of the Müller maneuver to RV resulted in generally small differences in any integral distribution. Intermap root-mean-square variability with these same interventions was also assessed and the results of this global assessment of map variability concurred with the spatial differences detected by the subtraction maps (Fig. 5). The least variability for all time integrals occurred with change in tidal volume. For all integrals, maps recorded at the extremes of respiratory volume were associated with the greatest variability ($p < 0.01$ versus tidal volume). For QRS and ST-segment time integrals, position change was also associated with a comparatively large map variability ($p < 0.01$ versus tidal volume).

The normalized root-mean-square variability data for the series of interventions showed that the P-wave time integral showed relatively greater variability than either the ST-segment or QRS integrals ($p < 0.01$); and the ST-segment variability was significantly greater ($p < 0.01$) than that of the QRS.

Discussion

The results of this study suggest that resting tidal volume respiration has relatively little effect on body surface ECG patterns. In contrast, change in posture from the supine to the upright position and large changes in respiratory volume may be associated with substantial changes in body surface ECG distributions. Although the P-wave integral showed the least absolute root-mean-square variability over the series of interventions tested in this study, it exhibited the greatest normalized or relative variation; the QRS integral, on the other hand, demonstrated the greatest absolute and the least relative variability. The relative constancy of the QRS wave form is consistent with results from other studies assessing temporal and exercise-associated P-QRS-T variability in normal subjects.[5,12]

Previous investigators, using both extensive[11] and limited[13–18] electrode arrays, have also described ECG changes associated with posture change and respiration. Our findings are in general agreement with those of the earlier studies, including the conclusion of Shapiro et

al[16] that postural ECG changes are greater than those that result from day-to-day variability of electrode locations. Our data suggest that this is also true for changes associated with maximal respiration.[5] The changes we found between maps recorded at the arrested end points of tidal respiration were, on the other hand, relatively small in magnitude and similar to the temporal variability previously described to occur during cyclic respiration with the same application of electrodes.[5] Similarly, our data are in agreement with those of Flaherty et al,[11] who described an inspiration-associated inferior torso shift and decrease of anterior QRS potentials in children. However, with our techniques we demonstrated that the inferior torso shift and decrease of QRS time-integral values with inspiration were marked only on deep inspiration.

Many explanations for the changes in the ECG appearances associated with position change and respiration have been proposed, including positional change of the heart in relation to the recording electrodes, alterations of vagal and sympathetic tone, differences of ventricular volume, variations in coronary artery flow and variations in electrical resistivity with changing lung volumes.[17] This study was not designed to resolve the underlying causes of ECG differences secondary to position change and respiration, but the results do suggest that the shifts in ECG distributions consequent to change from the supine to the upright posture and with maximal respiratory volume are associated with a similar physiologic change, most probably a common downward shift of the cardiac electrical source in relation to the recording torso electrodes. Although deep inspiration resulted in similar spatial shifts of P-wave and QRS distributions, there was a contrasting effect on the values of the P-wave and QRS maximums (P-wave maximum was unchanged and the QRS maximum decreased). These findings suggest that although large lung volumes may have a significant insulating effect on cardiac potentials during ventricular depolarization, they do not appear to affect all cardiac potentials equally. Because, in the absence of any other factor, one would reasonably expect a common insulating effect on all ECG potentials with increased lung volumes, these findings suggest that other factors are operative. These presumed other factors associated with deep inspiration, for example, increased intracardiac blood volume or change in sympathetic tone, may have contrasting effects to the increased electrical resistivity produced

FIGURE 5. Mean P-wave, QRS and ST-segment subtraction maps spatially locating the areas of difference for each time integral between sequential maps recorded at the following: supine and upright positions; end points of tidal (inspiration − FRC) and maximal (TLC − RV) respiration; and end points of maximal respiration with Valsalva (TLC − Valsalva) and Müller (RV − Müller) maneuvers. **Solid lines,** torso areas where maps recorded at the time of the previous intervention had greater integral value than maps recorded at the succeeding intervention; **interrupted lines,** areas where the previous maps had relatively less integral values compared with the succeeding state. The greatest areas of difference occurred between maps recorded at TLC and RV, that is, with maximal respiration; the least areas of difference occurred between maps recorded at the end points of tidal respiration. Blank maps indicate no differences in time-integral values greater than 1 μV·s between interventions. Abbreviations as in Figure 3.

by the increase in lung volume. Although these hypothesized, contrasting other factors may not manifest an effect on the large potentials of ventricular depolarization, they may exert a significant effect on the relatively much smaller potentials associated with atrial depolarization and ventricular repolarization.

The major implication of these findings is that ECG changes associated with other interventions, but including posture changes or respiration (for example, during exercise testing or in the course of ambulatory ECG monitoring), may be difficult to differentiate from those induced by respiration or posture change alone. Further work is required to define more fully the spectrum of body surface ECG changes in other physiologic states and in other populations (for example, patients with coronary artery disease) and to further explore the underlying electrophysiologic mechanisms of these changes.

An Ambulatory Ventricular Function Monitor: Validation and Preliminary Clinical Results

RICHARD A. WILSON, MD, PAUL J. SULLIVAN, MD, RICHARD H. MOORE, BA, JASON S. ZIELONKA, MD, NATHANIEL M. ALPERT, PhD, CHARLES A. BOUCHER, MD, KENNETH A. McKUSICK, MD, and H. WILLIAM STRAUSS, MD

A device for the continuous measurement of left ventricular (LV) function was tested in a series of 34 subjects. The instrument consisted of 2 arrays of radiation sensitive cadmium telluride detectors held in place over the region of the left ventricle and lung by a vest-like garment (hence the name VEST). The VEST electronic instrumentation included analog-to-digital converters, a battery pack, microprocessor and gating device, which were worn in a back pack. Data generated by the VEST, including the digitized average electrocardiogram, RR interval, counts/13 ms in each radiation detector, and time since commencement of data recording, were recorded on a cassette tape recorder every 2 minutes for subsequent analysis. At the conclusion of conventional multigated blood pool imaging, the VEST was positioned and worn by the subjects while supine, standing in place and walking. The correlation of ejection fraction calculated independently from the VEST and scintillation camera data was >0.95. The inter-record reproducibility of the ejection fraction measured by the VEST in sedentary subjects was <3%.

(Am J Cardiol 1983;52:601–606)

Radionuclide angiography at rest and exercise is frequently used to define both basal and reserve left ventricular (LV) function in patients with a wide array of cardiac disorders.[1–5] The stress commonly used for the procedure, large-muscle dynamic exercise, may not be representative of the types of everyday stress placed on the patient.[6] While performing ordinary activities of daily living, such as eating a meal, psychologic stresses or exposure to severe temperature changes, LV function may vary over a wide range in both the healthy and diseased heart. The changes in LV function brought about by these activities may equal or exceed those during the performance of a large muscle dynamic exercise test. To measure LV function while patients carry out their usual daily activities requires a means of measuring LV function outside of the hospital environment. In 1979 a device was constructed that would permit the ambulatory measurement of LV function.[7,8]

In this report we describe the initial results from a series of sedentary and ambulatory subjects with the prototype ambulatory LV function monitor, designed to be carried in a garment (VEST). This instrument simultaneously records the patient's average electrocardiogram, heart rate and nuclear data from the left ventricle and lungs in a form suitable for calculating LV ejection fraction and relative pulmonary blood volume.[9]

Methods

The ambulatory ventricular function monitor (VEST): The VEST consists of a pair of solid-state radiation detectors, gating apparatus, microcomputer and data recorder (Fig. 1). The instrument records the digitized electrocardiographic wave form averaged over 2 minutes, RR-interval histogram, and summed counts/13 ms from 2 radiation detectors, 1 placed over the left ventricle and 1 placed over the lungs. Commencing with the R wave, the count data from each nuclear detector is entered into a buffer memory each 13 ms. When the next R wave occurs, the process commences for the next beat into another memory. The previous cycle is then tested to determine if its length is within ±20% of the average of the previous 4-beat interval. If so, the data are considered normal and are added to those recorded previously in the average data buffer; those that are short or long are filed separately. Every 2 minutes, the information in memory is recorded on a capstan-drive pocket tape recorder for evaluation at the conclusion of data collection.

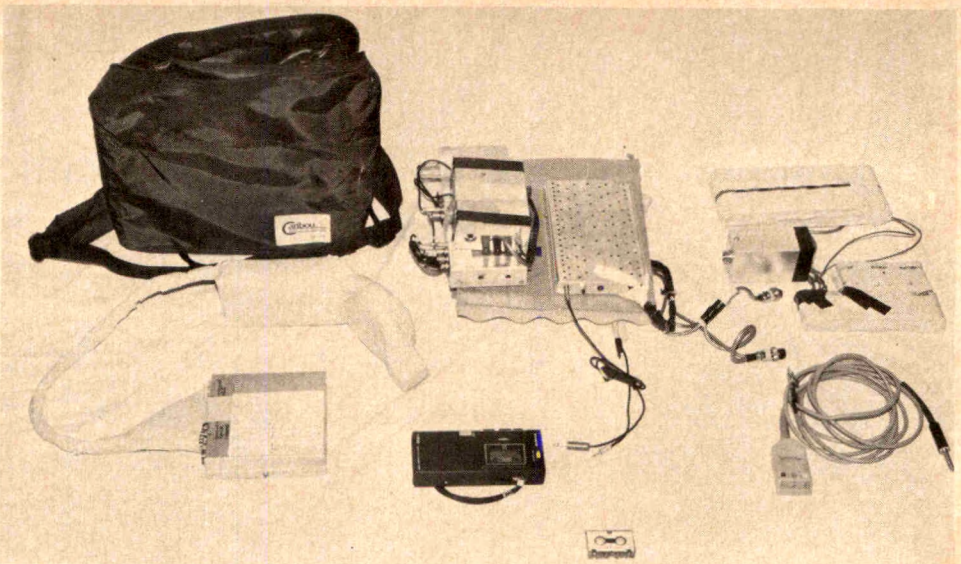

FIGURE 1. Top, VEST components in backpack. **Bottom,** exploded schematic of individual modules.

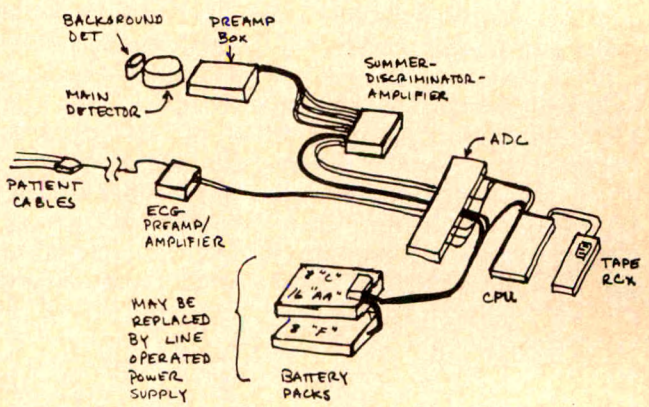
The radiation detectors consist of cadmium telluride crystals placed behind parallel-hole collimators (Fig. 2). After initial amplification, the output from the LV and lung background detectors is subject to threshold analysis and the composite signals are summed for 13 ms and recorded in the computer memory. The electrocardiographic data are digitized and stored in parallel with the nuclear data.

At the conclusion of the acquisition, the tape is read into a nuclear medicine computer and the R-R histogram, electrocardiogram and time-activity curves are calculated and displayed from each detector.* From these data the average heart rate, number of aberrant beats, LV ejection fraction and relative pulmonary blood volume are calculated for each time interval.

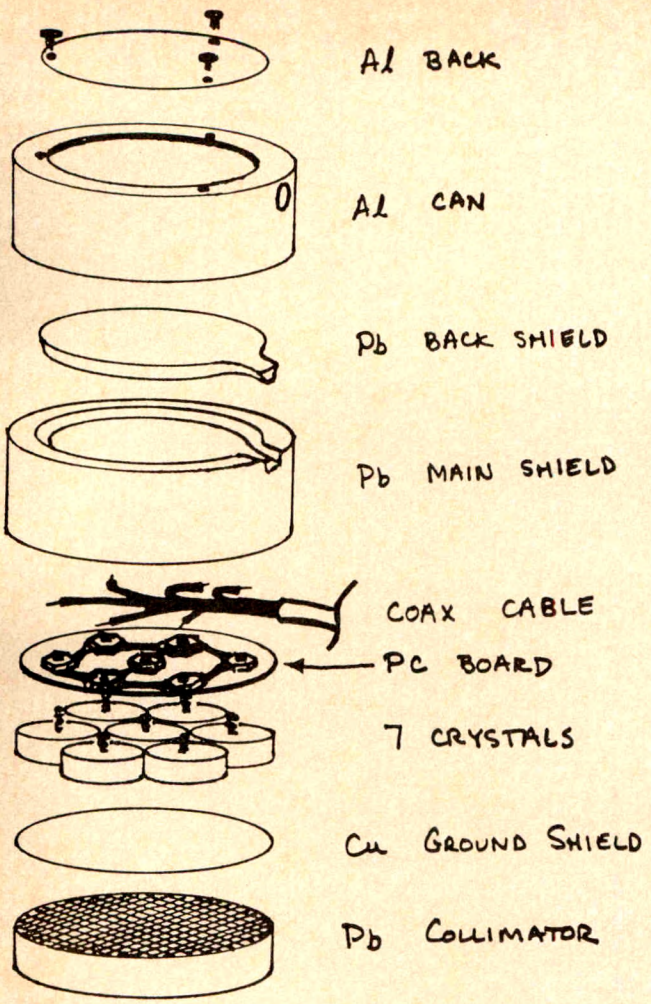
Patient studies: Multigated blood pool images were recorded in 26 patients (23 men and 3 women) as part of their evaluation for known heart disease. After in vivo red blood cell labeling as described by Callahan,[10] baseline multigated imaging was performed with a Technicare 420 scintillation camera equipped with an all-purpose, low-energy, parallel-hole collimator in the anterior, left anterior oblique and left posterior oblique views.[11] The data were recorded in a dedicated nuclear medicine computer system (Technicare 550) in a 16-frame (anterior and left posterior oblique) or 32-frame (left anterior oblique) 64 × 64 word mode matrix. At the conclusion of blood pool imaging, the persistence oscilloscope of the gamma camera was used to position the VEST foreground detector over the left ventricle in the 35 to 50° left anterior oblique projection that best separated right and left ventricles. The background detector was placed over a left paraventricular region that did not contain the descending aorta or spleen. The position of the VEST detectors was confirmed by acquiring a 30-second static image with the gamma camera (Fig. 3). The VEST detectors were affixed to the patient's chest with a sling and an elastic binder (Fig. 4). The batteries, microprocessor and tape recorder were carried in a small backpack. The weight of the entire apparatus is 5.5 kg.



To compare the VEST ejection fraction to that recorded with the scintillation camera, an initial set of VEST data (4 to 6 minutes) were recorded with the patient supine. The gamma camera was then moved aside and the patient was brought to a standing position for 6 to 8 minutes longer. The VEST was then removed and a second set of scintillation camera images was recorded in the standing position. In 15 patients who were too ill to stand, continuous data were recorded in the supine position. The ejection fractions were then determined independently by 2 observers: 1 calculated the ejection fraction from the gamma camera data with a varying region of interest count-based method and 1 analyzed the numerical data from the VEST.

Eight additional patients wore the VEST apparatus for ≤30 minutes while performing some ordinary activities in the hospital, such as walking in the hall, using the bathroom, sitting and reading, and quiet conversation. Gamma camera confirmation of ejection fractions were obtained in these patients in the sitting position, just before initial placement of the VEST, and in the standing position at the conclusion of VEST data recording.

*Differences in main detector (FG) and background detector (BG) sensitivities were determined using a technetium-99m flood source. The ratio of FG to BG probe sensitivities was then used to correct for the lower sensitivity of the background probe. The measured correction factor of FG = 2.3 × BG was found to remain stable over time. Confirmation of this correction factor was obtained before each patient study. Background counts multiplied by the correction factor were subtracted from the data recorded by the FG detector to generate the LV function curve. No other correction factors were used to calculate LV ejection fraction from the VEST.



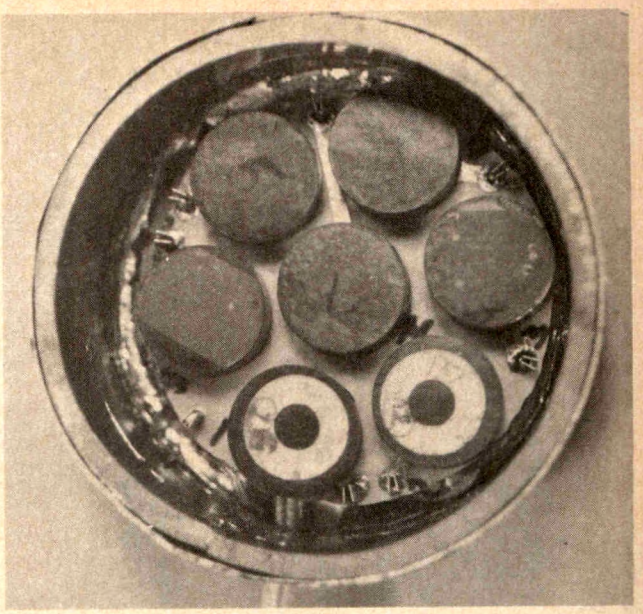


FIGURE 2. Left, main detector assembly, exploded view. **Right,** detector mosaic in housing viewed from patient side.

Ejection fractions calculated from the VEST data were compared with those calculated from the scintillation camera multigated images using a least-squares linear regression analysis.

Results

Correlation between the VEST and gamma camera–acquired LV ejection fractions are shown in Figure 4 for the supine-standing studies and in Figure 5 for ambulatory patients. For the supine/standing subjects, the LV ejection fraction correlation coefficient was 0.95 in both the supine and standing positions ($y = 1.49 + 0.98x$) (37 measurements on 26 patients, since some subjects were too ill to stand). Ejection fractions <50% (gamma camera) were observed in 16 patients. The correlation coefficient in this group was 0.92. In the sitting and ambulatory situations, the VEST and gamma camera ejection fraction correlation coefficients before and after ambulation were 0.98 ($y = 5.0 + 0.98x$) ($n = 8$). A comparison of the ejection fraction measured with the VEST on a single 2-minute record to that observed in the next 2-minute record revealed a record-to-record variation of <3%.

The results of a representative patient study recorded during the ambulatory validation phase are shown in Figure 6. The rest sitting ejection fractions determined during the first 8 minutes of the study are quite constant and closely match the LV ejection fraction obtained from the gamma camera before attachment of the VEST apparatus. During ambulation over the next 6 minutes, the ejection fraction increases slightly and after ambulation, with the patient standing, the ejection fractions from the VEST and gamma camera are similar.

Discussion

A practical nonimaging device for the repetitive measurement of LV function after equilibration of an intravascular tracer was described in 1976 by Wagner et al.[12] Initial studies with the instrument identified the requirement for precise positioning of the detector over the left ventricle to assure a correct measurement of LV ejection fraction.[13–16] Even with the positioning problems, however, investigators who have mastered the "positioning algorithm" have found excellent correspondence between gated probe measurements of

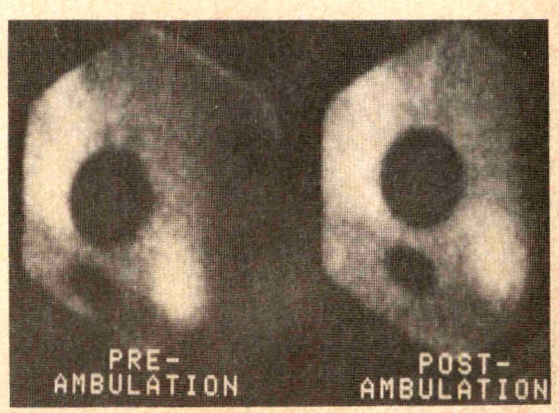

FIGURE 3. Pre- and postambulation positioning images.

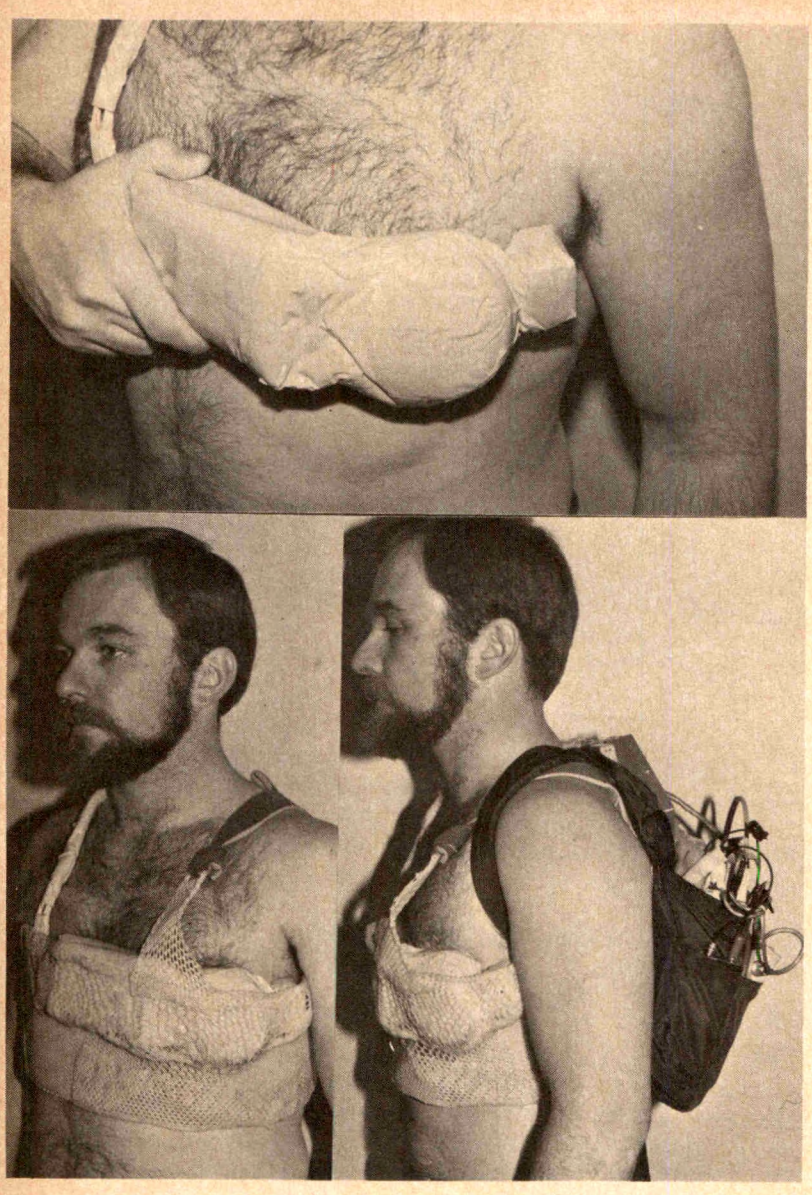

FIGURE 4. Top, detectors and preamplifier assembly on chest. **Bottom,** VEST on volunteer demonstrating thorax geometry and support device.

ejection fraction and those recorded with a gamma camera or contrast ventriculography.[13] The purpose of the VEST is to extend the ability to make continuous measurements of LV function from the bedside to an ambulatory environment. The prototype instrument digitizes, averages and records the electrocardiogram and time-activity curve data from two nuclear detectors to a cassette tape for subsequent analysis. Since this prototype was developed, state of the art electronics would now permit the simultaneous recording of additional physiologic variables, such as blood pressure and ventilatory function, in parallel with the multilead ECG and radionuclide data. These additional measurements will be particularly helpful to characterize changes in LV function during daily activities.

A critical problem with the VEST is the ability to initially place the detectors over the left ventricle and lung and to maintain this relationship during ambulatory activities. This was accomplished by placing the flat, small, radiopaque VEST detectors under direct vision using the scintillation camera persistence oscilloscope. The detectors were positioned to obscure the LV silhouette in the left anterior oblique position that best separated the left ventricle from other chambers and great vessels before fixation. Fixation of the device to the chest was accomplished with a harness and sling apparatus, similar to that used in women's foundation garments.

The correlation between ejection fraction measured with the VEST apparatus and that determined by the gamma camera in the sedentary patients suggest that technical portions of the VEST work properly. The ability to hold the detectors in place during mild physical activities was investigated in the 8 ambulatory subjects. The correlation between the VEST- and gamma camera–determined ejection fraction at the commencement and conclusion of monitoring suggest that the apparatus remained appropriately positioned with reference to the heart during these activities. Although 3 women were evaluated with the VEST with

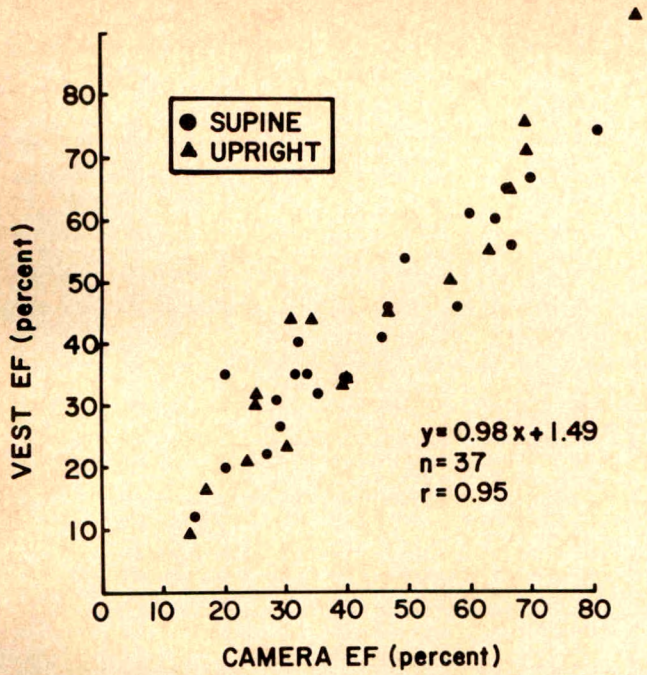

FIGURE 5. Gamma camera ejection fraction (EF) versus VEST EF (r = 0.95, n = 37, range 12–50%).

good results, fixation of the VEST detectors to persons with excessive fat or breast tissue may be difficult. However, the series of patients evaluated both supine and upright span a range of body habitus from lean to moderately corpulent.

An indication of the significance of cardiac/chest wall motion on the measured ejection fraction should be apparent when a patient changes from the supine to the standing position. The correlation of the VEST ejection fraction to that of the gamma camera under this circumstance remained good. These observations suggest that the instrument can be positioned to measure LV function and will provide valid data during the performance of moderate physical activities. The VEST data indicated no meaningful change in ejection fraction for the group of patients when changing from the supine to the upright position, probably because these patients had heart disease. This observation differs from that of Poliner et al[17] with the scintillation camera in healthy volunteers, in which a small increase in LV ejection fraction was observed from the supine to the sitting position.

The prototype VEST device[7,8] was designed to monitor electrocardiographic information and LV function for ≤24 hours. This is feasible, based on recent experience with improved red cell labeling techniques, which permit imaging of patients for gastrointestinal bleeding for >24 hours.[18] After administration of 20 mCi of technetium-99m red cells labeled with the modified in vivo method, the count rate of the main detector was high enough to permit collection of adequate data to calculate the ejection fraction in <15 seconds. Over 24 hours, the biologic loss of label from the red cells is minimal, while physical decay causes a 16-fold decrease in count rate. Therefore, a data collection interval of 240 seconds is required to calculate the ejection fraction with the same statistical reliability as would be available immediately after injection. This could be achieved either by adding data from sequential time intervals together (for 26- or 39-ms sampling throughout the cardiac cycle) or summing 3 sequential records. This endurance aspect of the instrument was not tested during this early phase of investigation.

The design criteria for the instrument were to simulate as closely as possible the qualities of a scintillation camera for determining ejection fraction. As a result, a parallel-hole collimator was selected, in contrast to the single-channel, tapered collimator used in the nuclear stethoscope device described by Wagner et al,[12] the probe device and probe simulation studies performed by Bacharach et al,[13] and the more recent studies by Hoffer et al[19] with a small cadmium telluride detector. To avoid the problems of sampling only a portion of a large dysfunctional ventricle, the foreground detector of the VEST was made large enough to sample activity from a major portion of, if not the entire, left ventricle (sensitive area >6 cm at the surface). This detector area is larger than that used by Hoffer et al[19] in their studies with a single cadmium telluride detector. These small technical changes may explain, in part, the better correlation of probe-determined ejection fraction in the present study (r = 0.95) compared with that reported by Hoffer et al (r = 0.76).

In contrast to previous studies using single probes, where pulmonary background activity was measured once, the VEST incorporates a second detector to permit continuous monitoring of blood pool activity in the lung. The additional data sought from this measurement (in addition to a background correction) is based on the studies by Nichols et al[20] and Okada et al.[9] These

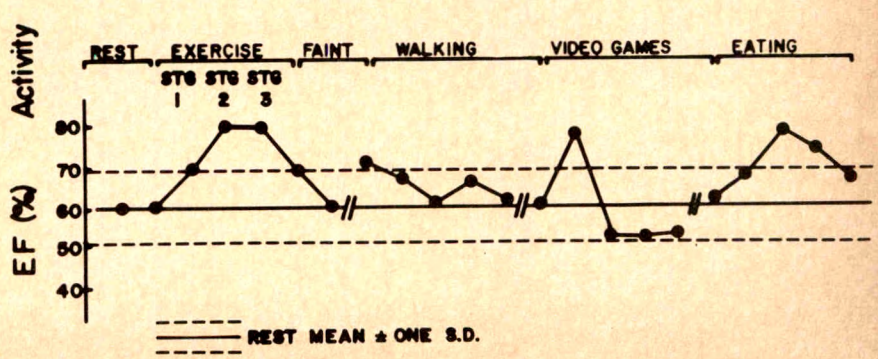

FIGURE 6. Pilot long-term monitoring study. EF = ejection fraction; S.D. = standard deviation.

investigators observed that the relative pulmonary blood volume, as measured by changes in the lung blood pool activity, is an independent and sensitive measure of alterations in LV function and, particularly, LV filling pressure.[21]

Although the anatomic and hemodynamic data obtained in the catheterization laboratory provide the basis for modern cardiac diagnosis, patients with less severe disease who are not candidates for catheterization may benefit from improved characterization of their myocardial perfusion and function available from noninvasive studies. Most of these measurements are accomplished in the laboratory, under rigorously controlled conditions. However, just as Holter ambulatory monitoring has added a new dimension to the evaluation of cardiac patients and the understanding of cardiac pathophysiology, it is likely that the ambulatory monitoring of ventricular function will also provide additional insights into the interaction of the patient's environment with his disease. Ambulatory electrographic monitoring has demonstrated an incidence of arrhythmias associated with activities of daily living that was unsuspected from monitoring limited to the laboratory.[22] For example, a patient may query whether a particular employment-related activity is safe. Although this is usually evaluated by a maximal stress test, the activity is never precisely reproduced outside the work environment. As a result, since each activity has a different impact on the heart in terms of myocardial oxygen demand or altered loading conditions, incorrect recommendations may be made, both in terms of excess conservatism and in implying safety for some excessively stressful activities. Therefore, a device like the VEST should offer important data to document the onset of cardiac decompensation.

Hydrogen Peroxide Contrast Echocardiography

F. ANDREW GAFFNEY, MD, JUI-CHIN LIN, MD, RONALD M. PESHOCK, MD, LARRY BUSH, PhD, and L. MAXIMILIAN BUJA, MD

Several agents are used as echocardiographic contrast agents, but their unreliability discourages routine clinical use. Studies from the early 1960s suggest that dilute hydrogen peroxide (H_2O_2) is a safe intravascular agent. Its use was evaluated in contrast echocardiography. To obtain dense opacification reliably, H_2O_2 (3%) was passed through a sterile 0.2 μm Millipore filter and diluted with heparinized saline solution to make a 0.1 to 0.2% solution. A drop of blood was withdrawn from an indwelling peripheral venous needle into a syringe containing 0.5 to 2.0 ml of the dilute H_2O_2 and the contents injected. Studies in dogs, normal adults and 36 patients with noncyanotic congenital and acquired cardiac disorders produced dense opacification with no complications. In vitro mixture of H_2O_2 (0.3%) with leukocyte-poor blood or plasma produced only a few microbubbles, while addition to whole blood or buffy coat produced many, suggesting a role for leukocyte peroxidase. H_2O_2 contrast echocardiography is simple, inexpensive, and reliably provides dense, sustained opacification. This study and previous studies suggest that intravenous injection of 0.2% H_2O_2 can be done safely. Great caution should be exercised in patients with severe pulmonary hypertension or large right-to-left shunts because little clinical experience with H_2O_2 is available. (Am J Cardiol 1983;52:607–609)

Contrast echocardiography is a well-recognized technique, useful in demonstrating a variety of cardiac disorders including atrial septal defect, ventricular septal defect, left superior vena cava, patent ductus arteriosus and tricuspid regurgitation.[1,2] Several contrast agents have been used in humans, including indocyanine green and aerated normal saline solution or 5% dextrose in water. Although these agents appear to be most widely used, other investigators have reported good contrast effect with the power injection of iodinated radiographic contrast material during ventriculography.[3] Surfactant-stabilized or gelatin-encapsulated microbubbles have been used in animal experiments, but appear to be too toxic for use in humans.[4,5]

Despite the ready availability of several echocardiographic contrast agents, contrast echocardiography does not appear to enjoy the widespread use one might expect. Reasons for this are not clear, but the lack of a safe, inexpensive agent that also reliably produces dense, sustained contrast effects with either M-mode or 2-dimensional echocardiography may be an important factor. Reports by Wang et al[6–8] in the People's Republic of China suggested that hydrogen peroxide (H_2O_2) might be such an ideal echocardiographic contrast agent. The present study examines this in detail.

Methods

Preparation of materials: H_2O_2, 3%, obtained from a local cosmetics firm, was passed through a 0.2μm Millipore filter and then diluted with heparinized normal saline solution (1 unit/ml) to produce a 0.2% solution of H_2O_2 (Table I). The solution was freshly prepared for each study to ensure sterility. A drop of blood mixed in vitro with 0.2% H_2O_2 produces foam and is a simple test of the activity of the H_2O_2 being used for study.

In vitro studies: Wang et al[6] suggested that the microbubbles were formed when the H_2O_2 reacted with leukocyte peroxidase and catalase to form water and oxygen. To examine this, we mixed the dilute heparinized H_2O_2 (0.3%) with small amounts of fresh human whole blood, plasma and leukocyte-poor blood. The presence or absence of bubble formation was determined with phase contrast microscopy.

Canine studies: Initial studies in 4 mongrel dogs revealed good reproducible microbubble formation, as evidenced by dense opacification of the right side of the heart on echocardiography, so further studies were performed to investigate potential adverse effects. Five awake, unsedated mongrel dogs were used after preparation and instrumentation as described in detail by Roan et al.[9] Left ventricular, left atrial and aortic pressures were measured and an electrocardiogram was obtained. Ultrasonic crystals were used to evaluate left ventricular segmental myocardial function. Serial injections of 1, 2, 5 and 10 ml of 0.3% heparinized H_2O_2 solution, activated with autologous blood, were made through the left atrial

TABLE I Method of Preparation of Hydrogen Peroxide (H_2O_2) for Injection

Hydrogen peroxide 0.3%
↓
0.2 μm Millipore filter
↓
Dilute to 0.2% with heparinized saline (1 U/ml)
↓
0.5–2.0 ml of dilute, filtered 0.2% H_2O_2 in small syringe
↓
Withdraw a drop of blood into the syringe, mix and inject immediately in right antecubital vein with butterfly needle

catheter to allow the microbubbles full access to the cerebral and coronary circulations.

Human studies: In initial studies performed in the investigators, 1 to 5 ml of heparinized 0.3% H_2O_2 solution was injected, but this amount often provided too much contrast effect (that is, a "white-out" of the right-sided chambers and vessels for 1 to 3 minutes) so smaller quantities were then used. Two milliliters of 0.2% H_2O_2 were used in all subsequent studies. Withdrawing a drop of blood into the syringe just before injection of H_2O_2 (0.2%) produced a much better contrast effect; this technique was therefore used in most studies performed in humans. The blood "activates" the process of microbubble formation; therefore, the blood-H_2O_2 mixture should not be left in the small volume of the syringe or large bubbles will form. Intravenous injection dilutes the mixture and may prevent coalescence of the microbubbles. Because the subject was usually in a left lateral decubitus position for optimal echocardiographic viewing, all intravenous injections were made with a small butterfly needle in the right arm. Venous return from the compressed left arm often produced delayed or diminished opacification. The electrocardiogram was monitored during and after the injection. Echocardiographic imaging was performed with a commercially available phased array sector scanner (Varian V-3000 and Hewlett-Packard HP-77020AC).

Results

In vitro studies: Virtually no bubbles were seen when H_2O_2 (0.2%) was added to leukocyte-poor blood or plasma. The ability of H_2O_2 to generate microbubbles could be restored to leukocyte-poor blood by returning the buffy coat to the mixture suggesting that white blood cells were necessary for rapid microbubble formation.

Canine studies: Left atrial injection produced no detectable changes in heart rate, aortic blood pressure, left ventricular dP/dt (first derivative of ventricular pressure) or segmental wall motion after any of these injections. In addition, the dogs seemed unaware of the injections. However, deliberate injection of 2.0 ml of foam produced by mixing H_2O_2 (0.3%) and canine blood evoked the expected responses (agitation, vocalization, ventricular ectopy and depression of segmental myocardial function).

Human studies: We performed initial studies on ourselves to determine the optimal quantities of H_2O_2 to be used for the desired contrast effect. Empirical testing led to the recommendations described above. No volunteer detected any sensation or unusual feeling in the chest after the injections, although the usual cold sensation and rarely a slight sting was felt at the injection site. No change in cardiac rate or rhythm occurred.

Studies were carried out in 36 patients. A variety of cardiac disorders, including atrial septal defect, ventricular septal defect, tricuspid regurgitation, pulmonary insufficiency, pulmonary hypertension, Uhl's anomaly and congestive heart failure, were examined. An example of the contrast effect routinely achieved with this technique is shown in Figure 1. Dense opacification of right-sided structures was achieved in all patients studied, and there were no detectable ill effects. Small amounts of right-to-left shunting were produced in 4 of 6 patients with atrial septal defects and in 2 patients with ventricular septal defects by performing the Valsalva maneuver. This confirmed the presence of the septal defect previously localized by a negative contrast effect, but produced no symptoms in any of the patients. No studies were conducted in patients with large right-to-left shunts because detection of these shunts

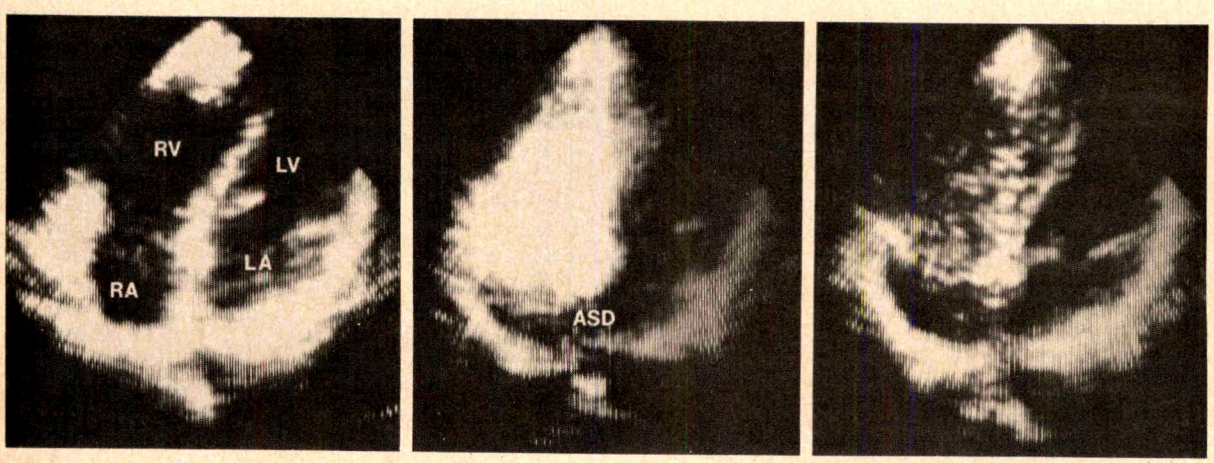

FIGURE 1. Hydrogen peroxide contrast echocardiography in a 25-year-old woman with a previously unrecognized ostium secundum atrial septal defect (ASD) and a 2.5:1 left-to-right shunt. **Left,** just before injection. **Center,** 8 seconds after injection. **Right,** 1 minute and 18 seconds after injection. Dense opacification is present except in the region of the ASD, where a negative contrast effect can be seen. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

does not require dense opacification, and aerated normal saline solution provides adequate contrast for this purpose.

Discussion

H_2O_2 is available directly from manufacturers in concentrations of 30 to 70% (wt %). These solutions are purchased by cosmetic firms and rebottled as the more dilute 3% H_2O_2 commonly sold in drug stores and other retail outlets. Deionized water is used as a diluent to prevent destabilization of the H_2O_2. The manufacturer usually adds tin and phosphate compounds for added stability and to prevent the tendency of chloride ions to pit and corrode aluminum storage vessels.[10] The American Chemical Society grade of H_2O_2 usually contains less than 20 ppm total residue on evaporation, although the highly stabilized grades contain as many as 4,000 ppm. In either case, injection of 1 to 10 ml of a 0.2% solution would not provide significant quantities of contaminants. Although the peroxide itself is bacteriostatic and fungistatic, Millipore filtering was performed before injection to eliminate particulate contamination.

Although not used for echocardiography, intravenous and intraarterial H_2O_2 injections have been used in many other clinical circumstances without apparent ill effects. These intravascular uses for dilute H_2O_2 have been described by several groups[11,12] and were reviewed by Urschel.[13] Wang noted that 6 of 11 patients with large right to left shunts developed lightheadedness, but did not note significant complications in 426 studies in 100 patients. As described previously, we used substantially lower concentrations and amounts of a purer preparation of H_2O_2, Millipore-filtered the solution and activated the microbubble formation in vitro before use and have performed over 150 injections without a single complication.

We did not introduce large amounts of oxygen microbubbles into the left side of the heart and circulation of the patients; it was not necessary clinically, and even though the oxygen should be better tolerated than air bubbles, both should probably be avoided as much as possible. Patients with large right-to-left shunts should be studied with as little contrast medium as possible to minimize the risk of the procedure. Aerated normal saline solution should be adequate for this purpose. Experience should be acquired in controlling the amount of contrast medium produced before examining patients with significant bidirectional or right-to-left shunts. Because of the unstable nature of patients with suprasystemic levels of pulmonary hypertension, any microbubble technique might produce complications and should be done with extreme caution, if at all. We did not attempt to produce myocardial opacification, although the doses used in our study were well within the nontoxic range recently reported by Gross et al[14] in a canine model.

Injection of the dilute, heparinized 0.2% H_2O_2 solution, preactivated with autologous blood, provides dense opacification of the right heart chambers and vessels. The microbubbles may be present for a few seconds to a few minutes, depending on the amount of contrast agent injected as well as venous return from the arm, the cardiac output and the presence of valvular regurgitation. Unless an intracardiac defect is present, peripheral venous injections do not produce visible left-sided microbubbles. This is consistent with other peripheral venous contrast agents, although injection from a pulmonary artery wedge position might be expected to produce a contrast effect on the left side of the heart.[15] Whether injection of massive amounts of H_2O_2 (0.2%) into the venous circulation would permit unreacted H_2O_2 to reach the arterial circulation is not known but is unlikely.

The present study was not designed to document the utility of contrast echocardiography in specific disease states, but rather to determine the safety and efficacy of a new agent, H_2O_2, for that purpose. In the small number of studies performed, H_2O_2 appears to be a safe, reliable and very effective agent. Although formal comparisons were not made with indocyanine green or specially aerated normal saline solution, the ability of H_2O_2 to produce dense, sustained contrast effects in every subject tested would appear to make it superior to other widely used agents. Dilute H_2O_2 (0.2%) is an extremely potent microbubble generator. As with any intravenous agent, care should be taken to provide sterility, correct dilution and the minimal effective dosage. As with any new agent, further studies in larger numbers of patients should be performed to confirm these findings.

Effect of Coronary Reperfusion on Myocardial Hemorrhage and Infarct Healing

CHARLES S. ROBERTS, BA, FREDERICK J. SCHOEN, MD, PhD, and ROBERT A. KLONER, MD, PhD

Early coronary reperfusion for treatment of acute myocardial infarction is a promising mode of therapy but may result in hemorrhagic infarction. The effect of hemorrhage on healing of myocardium subjected to early reperfusion is unknown, but could be detrimental. To compare repair of reperfused infarcts and permanently ischemic infarcts, 2 coronary arteries were occluded in 14 anesthetized dogs, and after 4 hours, 1 artery was reperfused. Either 1 or 14 days later, samples from the center of the infarcts and from normal myocardium were analyzed for hemoglobin (milligrams per gram), creatine kinase (international units per milligram of protein), and hydroxyproline (micrograms per gram) content. In an additional 7 dogs killed at 3 days after coronary occlusion, the myocardium was studied histologically. Gross subendocardial hemorrhage was present in all reperfused infarcts at 1 day; hemoglobin content was 8 ± 1 in normal myocardium and 10 ± 2 in permanently ischemic infarcts, but was highest in reperfused infarcts at 38 ± 7 ($p < 0.025$ versus permanently ischemic infarcts). Creatine kinase content in reperfused infarcts and permanently ischemic infarcts was similarly depressed (4 ± 2 and 7 ± 1 compared with 30 ± 5 in normal myocardium, $p < 0.05$). At 3 days, polymorphonuclear leukocyte infiltration was less prominent in reperfused infarcts than in permanently ischemic infarcts. At 14 days, hydroxyproline levels were similar in reperfused infarcts (9.4 ± 2.7) and permanently ischemic infarcts (10.7 ± 1.9), and higher than in normal myocardium (3.3 ± 0.4). Thus, intramyocardial hemorrhage occurs early in reperfused infarcts, is more severe than in permanently ischemic infarcts, and is associated with an altered early granulocyte response, without affecting late collagen formation.

(Am J Cardiol 1983;52:610–614)

Reperfusion of occluded coronary arteries by thrombolytic agents or by surgery has become a promising investigative therapy for acute myocardial infarction (MI). Although several investigators have shown that early reperfusion may salvage myocardium in the subepicardial portions of the ischemic zone,[1–3] experimental and clinical reperfusion may result in morphologic differences of the necrotic myocardium compared with nonreperfused infarcts, including the presence of interstitial hemorrhage and prominent myocyte intracellular contraction bands.[4–11] How these morphologic differences affect the healing process of the resultant myocardial necrosis is largely unknown. This study examines the early and late effects of reperfusion on the healing of regions of temporarily ischemic and permanently ischemic myocardium in the same dog.

Methods

Thirty-three mongrel dogs of either sex that weighed 14 to 27 kg were sedated with acepromazine maleate (1.0 mg/kg subcutaneously), anesthetized with sodium pentobarbital (30 mg/kg intravenously), intubated, and ventilated with a Harvard respirator. The carotid artery was cannulated to monitor arterial pressure in dogs with 1 and 14 days of coronary occlusion and the external jugular vein was cannulated to administer drugs when appropriate. A left thoracotomy was performed through the fifth intercostal space and the heart was suspended in a pericardial cradle. The mid-left anterior descending coronary artery was isolated below the first diagonal branch (approximately 4 cm from the left ostium), and the obtuse marginal branch of the left circumflex coronary artery was isolated at its origin.

Each dog was treated with a bolus of lidocaine (1.5 mg/kg intravenously), and 1 isolated coronary artery was occluded

TABLE I Hemoglobin Content (mg/g wet weight)

	Age of Infarct	
	1 Day	14 Days
Nonischemic myocardium	8 ± 1	6 ± 1
Reperfused infarct	38 ± 7*	9 ± 2†
Nonreperfused infarct	10 ± 2	10 ± 2

* $p < 0.025$ versus nonreperfused infarct.
† $p < 0.005$ versus 1 day.

TABLE II Hydroxyproline Content (μg/mg dry weight)

	Age of Infarct	
	1 Day	14 Days
Nonischemic myocardium	2.6 ± 0.3	3.3 ± 0.4
Reperfused infarct	2.2 ± 0.3	9.4 ± 2.7*
Nonreperfused infarct	2.4 ± 0.3	10.7 ± 1.9†

* $p < 0.025$ versus 1 day.
† $p < 0.005$ versus 1 day.

with a Schwartz vascular clip. At 5 minutes, a second bolus of lidocaine was administered and the other isolated coronary artery was permanently tied off with a silk suture. At 4 hours, the Schwartz clip was removed from 1 vessel to allow reperfusion. The chest was then closed and the dog was weaned off the respirator. This double-occlusion model is similar to that used by Genth et al[12] and allows a comparison of the healing process of a reperfused and a nonreperfused infarct within the same heart. By reperfusing at 4 hours and not earlier, our object was to produce equally sized reperfused and nonreperfused (permanently ischemic) infarcts within the same heart. The coronary artery used for the permanent versus the temporary occlusion was alternated from dog to dog.

At 1 day, 3 days or 14 days after occlusion, the dogs were reanesthetized, intubated and ventilated as before. After the chest was reopened, an overdose of potassium chloride was administered and the heart immediately excised and placed on ice. The right ventricle, left atrium and fatty and valve tissue were dissected away. The left ventricle was then sliced into transverse sections parallel to the atrioventricular groove.

In dogs killed at 1 or 14 days, myocardial tissue was analyzed biochemically for degree of necrosis (creatine kinase [CK]), hemorrhage (hemoglobin [Hb] concentration) and scar formation (hydroxyproline [HP] content). A fresh sample (mean ± standard deviation 0.64 ± 0.22 g) was taken from the center of the reperfused MI, the center of the nonreperfused MI and from remote normal myocardium, and placed in cold saline solution to be analyzed for Hb and CK content. The tissue samples contained 50 to 60% of the infarcted left ventricular ring. Hb concentration was analyzed spectrophotometrically as previously described[8,13,14] and expressed as milligrams per gram of wet weight of the sample. CK and cardiac protein were measured by the methods of Lowry et al[15,16] and CK was expressed as international units per milligram of protein. A 50- to 100-mg sample was taken from the center of the reperfused MI, the center of the nonreperfused MI, and from remote normal myocardium for HP content which was assayed by the method of Neuman and Logan[17] and expressed as micrograms per milligram of dry weight.

Seven animals were killed at 3 days to assess the morphologic features of early healing. From the hearts excised at 3 days, large samples were cut that encompassed both the reperfused MI and the nonreperfused MI at several levels. These samples were fixed in 10% buffered formalin, embedded in paraffin and sectioned at 6 μm. Three to 7 sections (mean 5), each stained with hematoxylin-eosin, were examined from each heart. The following histologic features of myocardial damage and repair were assessed qualitatively as absent, mild, moderate or severe: necrosis, contraction bands, hemorrhage and polymorphonuclear and mononuclear leukocytic infiltration.[18,19]

In hearts analyzed at 1, 3 and 14 days, a gross assessment of the presence and character of infarction and hemorrhage was made before fixation, and the transverse slices of each heart were placed under a clear acetate sheet in order to trace the infarcted and noninfarcted zones on clear plastic sheets. The slices were subsequently photographed. The size of each infarction was determined by planimetry and expressed as a percentage of the left ventricle.

All biochemical and planimetric data are presented as mean ± standard error of the mean, and paired t tests were used to compare infarcts within the same heart; group t tests were used to compare 1- and 14-day-old infarcts.

Results

Of the 33 dogs that entered the study, 12 were excluded: 1 died upon occlusion, 8 died during the reperfusion phase and in 3, at least 1 infarction was absent. Of the remaining 21 dogs, 7 were killed at 1 day, 7 at 3 days and 7 at 14 days. Analysis of Hb and HP content was successful in all hearts; CK measurement was unavailable in 3 dogs; histologic analysis of 1 dog that died 2 days after occlusion was included.

The biochemical data from infarcts subjected to 1 and 14 days of coronary occlusion are listed in Tables I and II. At 1 day there was approximately 4 times more Hb in the reperfused MI than in the nonreperfused MI (Table I) and HP content was low in remote normal myocardium, reperfused MI and nonreperfused MI (Table II). CK levels were similar in reperfused MI (4 ± 2 IU/mg protein) and in nonreperfused MI (7 ± 1 IU/mg protein, p = NS [not significant]), but were significantly lower than in remote normal myocardium (30 ± 5 IU/mg of protein; $p < 0.05$).

At 14 days, Hb levels were significantly lower than at 1 day in reperfused MIs (Table I), which may be due to reabsorption of or denaturation of hemoglobin within the reperfused infarcts. At this time, Hb levels were similar in reperfused and nonreperfused MI. HP levels in both infarcts were significantly higher at 14 days than at 1 day (Table II). HP content was similar at 14 days in the reperfused and nonreperfused MI and higher in reperfused MI than in remote normal myocardium. At 14 days, CK levels were significantly and similarly lower in both infarct groups (22 ± 5 IU/mg protein in reperfused MI and 16 ± 8 IU/mg protein in nonreperfused MI) compared with values in remote normal myocardium (41 ± 3 IU/mg protein, $p < 0.025$). CK levels within the infarcts tended to be higher at 14 days than at 1 day.

Upon gross analysis, hemorrhage in the nonreperfused MI at 1 day was severe, dark red and confined to the inner one half of the left ventricular wall. A rim of necrotic but nonhemorrhagic tissue often surrounded

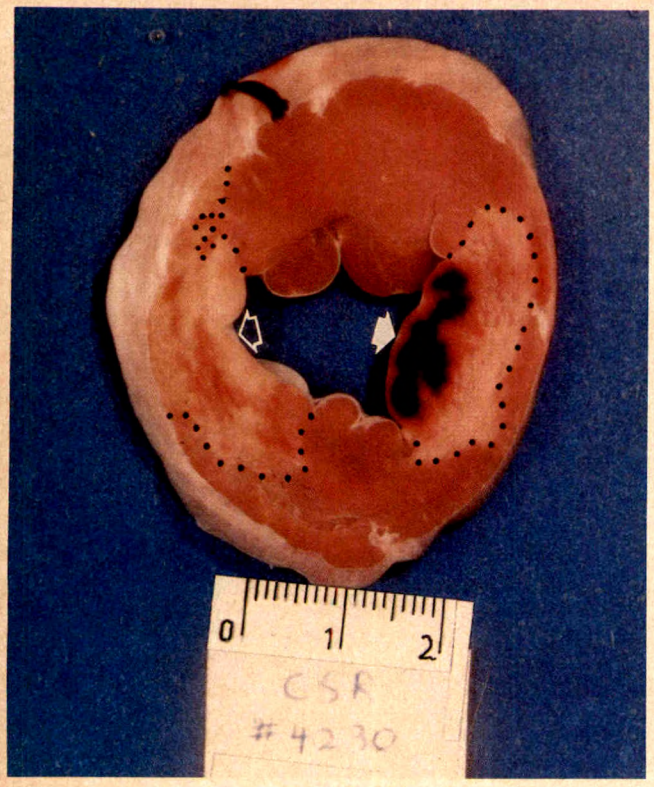

FIGURE 1. Transmural left ventricular slice from a dog that underwent 4 hours of coronary occlusion followed by 1 day of reperfusion of the circumflex coronary bed and permanent coronary occlusion of the left anterior descending coronary bed. The reperfused infarct on the right (**solid arrow**) shows an inner dark brownish hemorrhage outlined by bright red hemorrhage confined to the subendocardium, surrounded by infarcted, nonhemorrhagic, pale tissue. The permanently ischemic infarct (**open arrow**) on the left shows more diffuse and mild hemorrhage.

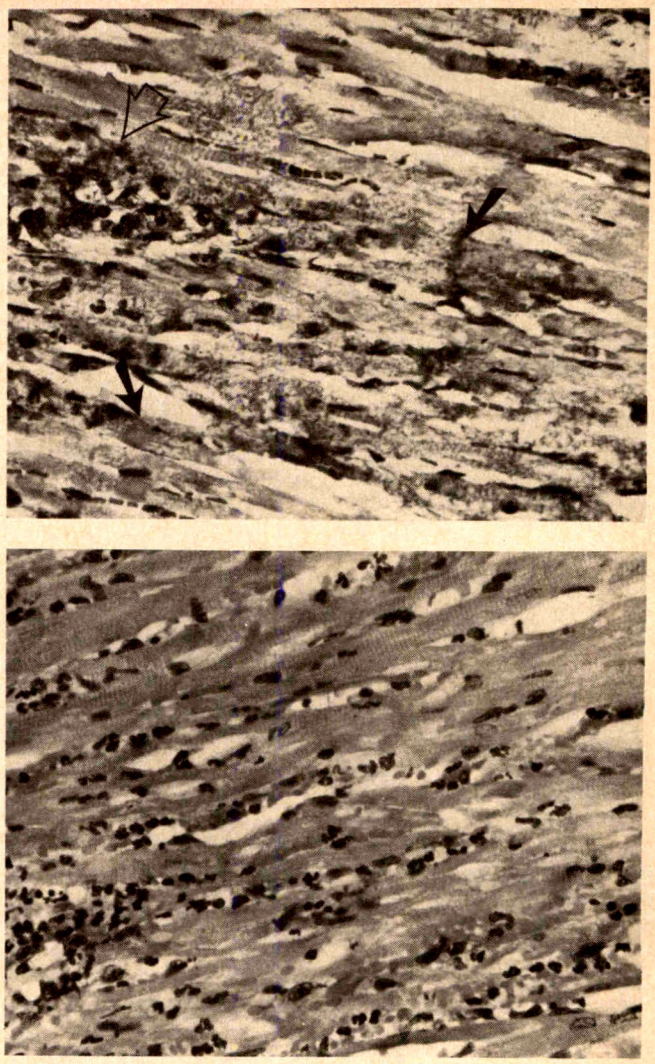

FIGURE 2. Histologic photomicrographs of infarct reperfused at 3 hours and a permanently ischemic infarct 72 hours after original ligation. **Top,** reperfused infarct demonstrating necrosis with contraction bands (**closed arrows**) and focal mononuclear cell infiltrate (**open arrow**). **Bottom,** permanently ischemic infarct with coagulation necrosis and diffuse polymorphonuclear leukocytic infiltrate. Hematoxylin-eosin stain; magnification ×375, reduced 23%.

the gross hemorrhagic region (Fig. 1). In contrast, hemorrhage in the nonreperfused MI at 1 day was mild and light pink.

The sizes of the reperfused and nonreperfused infarcts determined by gross pathologic analysis and planimetry at 1, 3 and 14 days were similar. At 1 day, the mean percentage of left ventricular area that was infarcted was 16 ± 4% for the reperfused MIs and 10 ± 2% for the nonreperfused MIs (p = NS); at 3 days, the mean percentage of left ventricular area was 12 ± 3% for the reperfused MIs and 10 ± 2% for the nonreperfused MIs (p = NS); at 14 days, the mean percentage of left ventricular area infarct was 8 ± 2% for the reperfused MIs and 9 ± 3% for the nonreperfused MIs (p = NS).

Histologic analysis of these infarcts at 3 days demonstrated that both reperfused and permanently ischemic infarcts were predominantly subendocardial, including large involvement of the papillary muscles. Although the degree of necrosis was similar in both groups, hemorrhage was absent to mild and had only small foci in permanent infarcts, while it was moderate to severe in reperfused myocardium and was localized in the subendocardium. Transverse eosinophilic contraction bands were seen at the edges of permanently ischemic infarcts but were not seen toward the center of the infarcts. They were more diffuse but similarly mild in reperfused infarcts. Histologic analysis of the dog that died at 2 days was similar to that of the dogs analyzed at 3-days.

The inflammatory response of these infarcts differed at 3 days. The polymorphonuclear leukocytic response was greater in permanently ischemic than in reperfused infarcts in the same animal. Polymorphonuclear inflammation was moderate in the permanently ischemic infarcts with multiple large foci (Fig. 2). Nevertheless, in reperfused infarcts, mild infiltration with occasional small foci was noted in nonhemorrhagic myocardium, and there was an overall tendency toward more mononuclear (histiocytic) inflammation in the reperfused infarcts. Figure 3 illustrates the different configurations of the infarcts.

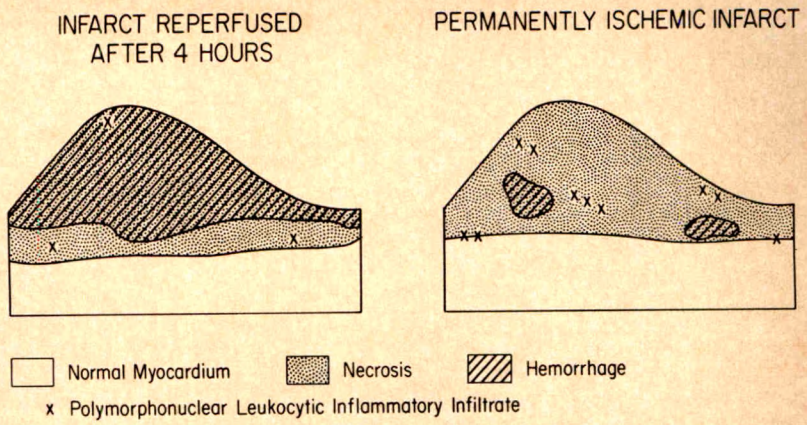

FIGURE 3. Relationship of infarct to hemorrhage and polymorphonuclear leukocytic inflammatory infiltrate at 3 days in this model.

Discussion

Deleterious effects of reperfusion hemorrhage on evolving MI have been reported by several investigators.[4–9] Extension of ischemic injury, impaired healing and functional disorders have all been implicated with intramyocardial hemorrhage. Bresnahan et al[8] suggested that hemorrhage due to coronary reperfusion leads to the extension of myocardial necrosis in the dog. Lie et al,[20] in a clinical study of patients with aortocoronary bypass and evolving MI, reported that hemorrhage not only extended the area of ischemic injury, but also impaired the histologically observed healing process. The necrotic muscle in hemorrhagic infarcts appeared dormant compared with the actively healing nonhemorrhagic infarcts.

In the present study, early hemorrhage in the reperfused infarcts was much more severe than that in the nonreperfused infarcts, as assessed grossly, histologically and by Hb content. This hemorrhage was typically located in the central and subendocardial portions of the infarction. Fishbein et al[21] and others[14] found hemorrhage only in areas of microvascular injury within the necrotic zone. The hemorrhage observed in the present study was confined to the necrotic zone and was most severe in the inner one half of the left ventricular wall, where microvascular damage would be greatest[22,23] (Fig. 1). In contrast, hemorrhage in nonreperfused infarcts at 1 day was mild, diffuse and not confined to any particular area of the ischemic zone.

Reperfusion appeared to alter the early polymorphonuclear leukocytic infiltration. At 3 days, granulocyte infiltration was less prominent in the infarction that had been reperfused, but mononuclear cell infiltration was often more prominent. It is conceivable that the granulocyte response either was suppressed throughout or had peaked at an earlier time, before biopsy. Other data,[10] however, suggest that granulocytic infiltration is not prominent at any time in the repair of this injury. The precise reason for the altered inflammatory response after reperfusion is not clear, but it may be related to the washout from the myocardium of complement-derived chemotaxins or other mediators known to be activated locally after lethal acute myocardial ischemic injury[24] or both. This phenomenon may be analogous to the rapid washout of CK demonstrated after reperfusion of myocardium with severe ischemic damage.[25] Nevertheless, there is strong evidence to suggest that the formation of granulation tissue is not dependent on the presence of neutrophils,[26] but is critically related to the action of mononuclear phagocytes.[27] The 3-day differences in the morphology of reperfused versus permanently ischemic infarcts could not be due to infarct size since the size of the infarcts was similar. HP concentrations in the center of the reperfused and nonreperfused infarcts were similar at 14 days. By gross assessment, scar size at 14 days was similar in the reperfused and nonreperfused infarct; however, the collagen content of the entire scar was not measured.

The present study assessed the effects of early reperfusion on the healing of infarction, rather than on infarct size. Previous studies,[1–3] including a recent study from this laboratory,[28] have shown that reperfusion at $\leq$3 hours of ischemia results in smaller infarcts. We did not reperfuse until 4 hours in the current study in order to create approximately equally sized reperfused and nonreperfused infarcts. This avoided the problem of interpretation that would have occurred if 1 group had smaller infarcts, which presumably might have healed more quickly than larger infarcts. Although reperfusion after coronary occlusion leads to hemorrhage into tissue that had been severely ischemic,[14] the question of how this hemorrhage may ultimately affect healing previously had not been determined.

This study suggests that intramyocardial hemorrhage induced by coronary reperfusion after 4 hours of ischemia affects the early healing process of myocardial infarction, resulting in altered neutrophil infiltration, but does not impair collagen formation. Hemorrhage was confined to the zone of necrosis.

Failure of Pretreatment With Propranolol to Reduce the Zone of Myocardial Infarction After 2 Hours of Coronary Occlusion in the Primate Heart

GRAYSON G. GEARY, MB, FRACP, LYNNE FENTON, GARY CHENG, GREGORY T. SMITH, PhD, BENJAMIN SIU, and J. JUDSON McNAMARA, MD

The present study assessed the value of pretreatment with propranolol to reduce ultimate myocardial infarct size after acute coronary artery occlusion in the primate heart. An experimental group of 8 baboons was administered a 2-mg/kg loading dose of propranolol intravenously over a 20-minute period before coronary occlusion. This regimen resulted in (1) a decrease in heart rate from 104 ± 19 to 73 ± 8 beats/min (mean ± standard deviation) ($p < 0.001$), (2) a decrease in the peak rate of rise of left ventricular pressure from 2,300 ± 340 to 1,365 ± 307 mm Hg/s ($p < 0.01$), (3) a decrease in cardiac output from 1,571 ± 249 to 1,287 ± 360 ml/min ($p < 0.001$), (4) an increase in left atrial pressure from 5.6 ± 1.9 to 9.9 ± 2.7 mm Hg ($p < 0.001$), and no significant change in mean arterial pressure. The left anterior descending coronary artery was occluded for a 2-hour period, after which perfusion was restored. A control group of 8 baboons underwent an identical procedure without propranolol therapy. At 24 hours after occlusion, microvascular dyes were injected into the coronary arteries to delineate the anatomic perfusion bed of the previously occluded coronary artery (region at risk to infarction). This allowed histologically assessed infarct size to be expressed as a percentage of the size of the perfusion bed of the occluded artery. The mean percentage of the perfusion bed infarcted in the control group was 54 ± 14% and in the treated group was 55 ± 21% (difference not significant). Hence, despite a significant decrease in heart rate and left ventricular contractility, pretreatment with propranolol did not reduce ultimate infarct size in the primate heart. The failure of propranolol therapy to result in infarct size reduction in the primate heart may be due primarily to the absence of a significant collateral circulation.

(Am J Cardiol 1983;52:615–620)

It has been proposed that propranolol, a beta-adrenergic blocking agent, may reduce myocardial ischemia after acute coronary occlusion by reducing myocardial oxygen demand. Several investigators have observed that propranolol has a beneficial effect during acute myocardial ischemia, as indicated by a decrease in creatine phosphokinase depletion within the ischemic region[1] and a reduction in histologically determined infarct size.[2–4] However, other investigators have not shown a beneficial effect of propranolol in decreasing ischemic injury, as indicated by a failure to affect myocardial tissue creatine phosphokinase depletion[5,6] or infarct size.[7] The reasons for these conflicting results have not been clarified. However, the discrepancy may, in part, stem from the fact that there is considerable variability in infarct size, even with coronary occlusion at the same anatomic site, due to inherent variability in the size of the anatomic perfusion bed of an occluded artery.[8] Failure to control for this source of variability may lead to considerable error in the assessment of the effects of a drug on infarct salvage. Therefore, in the present study, the effect of propranolol on infarct size was examined by comparing histologic infarct size as a percentage of the anatomic perfusion bed of the occluded artery (region at risk to infarction) between control and treated baboons. This provides for a more accurate quantitative assessment of the effect of propranolol on infarct salvage. In addition, the importance of collateral

flow to a region of ischemia in mediating the effects of propranolol was assessed by using a primate model with minimal coronary collateral circulation.[9,10]

Methods

Surgical preparation: Sixteen baboons (*Papio anubis*) that weighed 13 to 18 kg were sedated with intramuscular ketamine hydrochloride (10 mg/kg). Anesthesia was induced and maintained by intravenous injections of sodium thiopental (2 mg/kg). Baboons were intubated with a cuffed endotracheal tube and ventilated with a Harvard volume respirator maintaining an arterial pH of 7.40 ± 0.05. Arterial pressure was monitored by an 8F catheter advanced through the femoral artery. Under sterile conditions, a left thoracotomy was performed and the heart suspended in a pericardial cradle. A 3-0 mersilene snare was placed around the left anterior descending coronary artery (LAD) distal to the first diagonal branch. An electromagnetic flow catheter (Millar Instruments) was inserted into the pulmonary artery to monitor cardiac output. Left atrial pressure was monitored by way of a catheter inserted through the left atrial appendage. Left ventricular (LV) pressure and the rate of rise of LV pressure were monitored by a Millar micromanometer-tip catheter inserted through the apex of the left ventricle. Two rows of 6 unipolar atraumatic epicardial electrodes (spaced at 5-mm intervals) were sutured to the left ventricle so that they overlay the anticipated region of ischemia. The electrocardiograms were monitored with a Gould Brush Mark 260 recorder at a paper speed of 25 mm/s and a sensitivity of 1 mV/mm.

Experimental protocol: After control baseline hemodynamic values were measured, an experimental group of 8 baboons was administered a loading dose of propranolol, 2 mg/kg intravenously, in 4 equally divided doses over 20 minutes. At 10 minutes before occlusion, hemodynamic measurements were repeated after 1 mg/kg of propranolol had been administered. At 2 minutes before occlusion, after a total dose of 2 mg/kg, hemodynamic measurements were repeated and control epicardial electrocardiograms were recorded. The LAD was then occluded by tightening the snare and hemodynamic measurements and epicardial electrocardiograms were recorded at 15-minute intervals. At 2 hours after occlusion, anterograde perfusion was restored by release of the occluding snare. A lidocaine bolus (1 mg/kg) was prophylactically administered intravenously immediately before occlusion and reperfusion. The left atrial, LV and pulmonary artery catheters were removed at 3 hours after occlusion (1 hour after reperfusion) and, after closure of the chest, the baboons were returned to their cages. One baboon in the treated group died postoperatively, presumably from a ventricular arrhythmia after being returned to its cage, and was excluded from further study. At 24 hours after occlusion, immediately before killing the baboons, a bolus of heparin (5,000 U) was administered intravenously to prevent postmortem clotting of blood within the coronary arteries and thus allow for subsequent microvascular dye injections. The baboons were then killed with a rapid infusion of a saturated potassium chloride solution (arresting the hearts in diastole) and the hearts were excised. A control group of 8 baboons underwent a protocol identical to that of the experimental group except that no propranolol was administered.

Perfusion bed delineation and histologic assessment: Catheters were placed into the LAD at the site of previous occlusion, the proximal LAD, the proximal left circumflex coronary artery, and the proximal right coronary artery. These arteries were then injected simultaneously with different colored silicone rubber microvascular dyes (Microfil, Canton Biomedical Products). We have described in detail this dye injection technique,[11] which allows for accurate delineation of the perfusion bed subserved by an occluded coronary artery. After fixation of the hearts in 10% formalin for 3 days, serial cross sections of the heart were made at 3-mm intervals parallel to the minor axis of the left ventricle. A microscopic slide was made from each cross section and stained with hematoxylin-eosin. The perfusion bed of the occluded artery was readily visualized on the paraffin tissue block of the LV cross section and was marked on the corresponding histologic slide by superimposing the slide on the tissue block. Microscopic examination of each histologic slide allowed the area of infarction also to be marked on the slide. The area of the perfusion bed and the area of infarction were determined by planimetry and the areas were multiplied by the thickness of each cross section to give the respective volumes for each section. Summation of the volumes of each tissue section yielded the total volume of the perfusion bed and total volume of infarction for each heart. A mean tissue density of 1.055 for all the baboons was then used to convert the total volume of the perfusion bed and the total volume of infarction for each heart to mass.

Statistical analysis: The significance of hemodynamic and histologic changes between the control and treated baboons was examined by using Student *t* test. All values are given as mean ± standard deviation.

Results

Hemodynamics: Table I summarizes the hemodynamic results for the control and treated baboons from baseline values at 20 minutes before occlusion until 1 hour after reperfusion. At 20 minutes before occlusion, there were no significant differences between the 2 groups in any of the hemodynamic measurements. The control group of baboons had no significant changes in any of the hemodynamic measurements in the 20-minute period before occlusion. At 10 minutes before occlusion in the treated group, after a total dose of 1 mg/kg of propranolol had been administered, there were significant hemodynamic changes compared with the values 20 minutes before occlusion: (1) Heart rate decreased from 104 ± 19 to 78 ± 8 beats/min ($p < 0.001$). (2) Peak rate of increase of LV pressure decreased from 2,300 ± 340 to 1,635 ± 318 mm Hg/s ($p < 0.001$). (3) Cardiac output decreased from 1,571 ± 249 to 1,312 ± 368 ml/min ($p < 0.05$). (4) There was a small increase in left atrial pressure from 5.6 ± 1.9 to 8.3 ± 2.4 mm Hg ($p < 0.01$). There was no significant change in mean arterial pressure. At 2 minutes before occlusion, after the total dose of 2 mg/kg of propranolol had been administered, there were further significant, but smaller, changes in hemodynamic values: (1) Heart rate decreased from 78 ± 8 to 73 ± 8 beats/min ($p < 0.01$). (2) Peak rate of rise of LV pressure decreased from 1,635 ± 318 to 1,365 ± 307 mm Hg/s ($p < 0.05$). (3) Left atrial pressure increased from 8.3 ± 2.4 to 9.9 ± 2.7 mm Hg ($p < 0.001$). Mean arterial pressure and cardiac output showed no significant change.

At 2 hours after occlusion, there was a small increase in left atrial pressure from 5.1 ± 0.9 to 6.7 ± 2.3 mm Hg ($p < 0.05$) in the control group when compared with the 2-minute values before occlusion. There were no significant hemodynamic changes observed in the treated group during this same period. There were no significant hemodynamic changes in either group of baboons between 2 hours after occlusion and 1 hour after reperfusion.

TABLE I Hemodynamic Values for Control and Treated Baboons From 20 Minutes Before Occlusion to 1 Hour After Reperfusion

	20 Minutes Before Occlusion	10 Minutes Before Occlusion	2 Minutes Before Occlusion	2 Hours After Occlusion	1 Hour After Reperfusion

AP = arterial pressure; CO = cardiac output; HR = heart rate; LAP = left atrial pressure; peak dP/dt = peak value of rate of rise of left ventricular pressure.

Results are mean ± standard deviation.

* Significant change ($p < 0.001$) compared with corresponding value at preceding time interval.

† Significant change ($p < 0.01$) compared with corresponding value at preceding time interval.

‡ Significant change ($p < 0.05$) compared with corresponding value at preceding time interval.

Comparison of histologic changes between control and propranolol-treated baboons: Cross sections of the left ventricle in both control and propranolol-treated baboons showed that the perfusion bed of the occluded coronary artery was readily delineated by the microvascular dye. Hemorrhage was observed within the perfusion bed of the occluded artery in both groups. A representative cross section of the heart in a control baboon is shown in Figure 1, which shows the distinct area of the perfusion bed of the occluded coronary artery and the centrally located hemorrhage region.

Microscopic examination of hematoxylin-eosin–stained cross sections showed that the areas of infarction were completely contained within the perfusion bed of the occluded coronary artery. Infarcts characteristically consisted of a central confluent zone of infarction surrounded by a peripheral zone of small foci of patchy infarction. The infarcts showed coagulation necrosis and involved the subendocardial and midwall regions of the perfusion bed, and myocardial preservation was observed in the subepicardial and lateral regions. Some contraction band necrosis was evident in the patchy regions of infarction but not in the central zone. Hemorrhage occurred extensively within the central area of infarction and, to a lesser extent, in the patchy areas of infarction in both control and treated baboons. No hemorrhage was observed outside of the infarcted regions.

Comparison between the percentage of the perfusion bed infarcted in control and propranolol-treated baboons: Figure 2 shows the percentage of the perfusion bed infarcted for both the control (n = 8) and

FIGURE 1. Cross section of the heart from a control baboon. The previously occluded left anterior descending coronary artery was injected with yellow microvascular dye and the adjacent arteries with red dye. The perfusion bed of the previously occluded artery is readily delineated and contains a central hemorrhagic region.

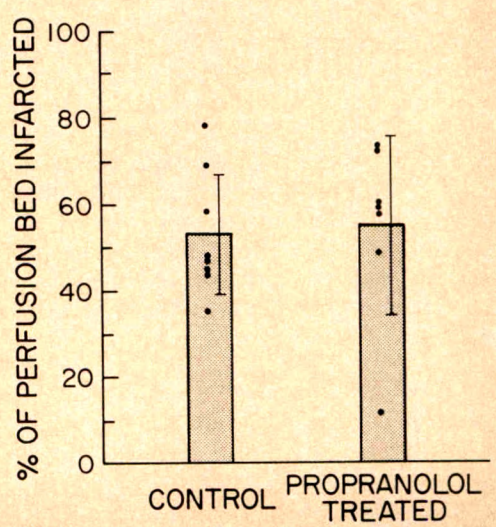

FIGURE 2. The percentage of the perfusion bed infarcted for control and propranolol-treated baboons.

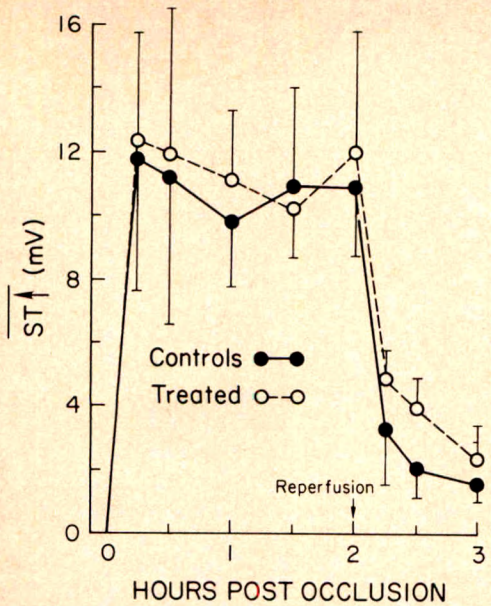

FIGURE 3. Epicardial ST-segment changes after occlusion and reperfusion in control and propranolol-treated baboons. $\overline{ST}\uparrow$ = mean ST-segment elevation.

treated (n = 7) baboons. The mean percentage of the perfusion bed infarcted in the control group was 54 ± 14 and in the treated group was 55 ± 21 (difference not significant [NS]).

A relatively consistent percentage of the perfusion bed was infarcted in both the control and treated groups, with the exception of 1 baboon in the treated group that had only 12% of the perfusion bed infarcted. The reason for this somewhat anomalous result was not evident; however, the control heart rate in this baboon was considerably slower than the others in the treated group. The control heart rate in this baboon was 68 beats/min, while the mean heart rate in the rest of the group was 109 beats/min. The heart rate after propranolol treatment was 57 beats/min in this baboon and the corresponding mean heart rate in the rest of the group was 75 beats/min.

Epicardial ST-segment changes: Figure 3 shows the epicardial ST-segment changes after occlusion and reperfusion in the control and treated baboons. Epicardial ST-segment elevation occurred immediately after occlusion and remained essentially constant during the period of occlusion in both groups, indicating ischemia of the underlying myocardium. Successful anterograde reperfusion after release of the snare was indicated by a rapid decrease in epicardial ST-segment elevation and the appearance of arterialized blood in the previously occluded artery.

Discussion

Propranolol, a beta-adrenergic blocking agent, has been widely used in experimental and clinical attempts to reduce myocardial ischemia after acute coronary artery occlusion. It has been proposed that propranolol may reduce myocardial ischemia by a reduction in myocardial oxygen consumption resulting from a decrease in heart rate and contractility.

A number of experimental studies have shown that propranolol has a beneficial effect in acute ischemia by (1) reducing epicardial ST-segment elevation within the ischemic region,[1,2,12,13] (2) reducing myocardial tissue creatine phosphokinase within the ischemic region,[1] (3) reducing histologic necrosis of the posterior papillary muscle,[4] and (4) reducing infarct size when expressed as a percentage of the left ventricle.[2,3] However, it has also been demonstrated that treatment with propranolol has failed to alter myocardial tissue creatine phosphokinase depletion after coronary occlusion[5,6] and did not result in infarct size reduction.[7] No obvious methodologic differences have been elucidated to explain these conflicting results with regard to the beneficial effect of propranolol in acute myocardial ischemia. It has been suggested that higher doses of propranolol are responsible for the failure to observe beneficial effects in ischemic injury; however, the "high dose" of propranolol used in the study of Peter et al,[5] in which a beneficial effect was not observed, was the same dosage used in several studies that demonstrated a reduction in infarct size with propranolol.[4,13] It may well be the case that propranolol, by virtue of its effects in reducing oxygen consumption, temporarily reduces the degree of myocardial ischemia; however, this does not necessarily mean an ultimate reduction in infarct size will result and may represent only a delay in the natural progression of necrosis within the ischemic region. The results of the present study, which used an accurate quantitative histologic technique of measuring infarct salvage, clearly demonstrated no decrease in long-term infarct size.

Clinical implications: Human myocardial infarction usually occurs in patients with long-standing coronary atherosclerosis who often have multiple-vessel involvement and some degree of collateralization. The impact of coronary occlusion may therefore be greatly modified by the presence of adjacent vascular lesions and by the collateral channels. Hence, the results of the present study cannot be directly extrapolated to the human situation, except perhaps for the case when acute thrombosis or embolization occurs in a single vessel in a patient with normal coronary arteries. In addition, propranolol may exert part of its action by modifying vagal or sympathetic responses, which are common in human myocardial infarction but which may be altered in the anesthetized animal. In man, the ability of propranolol, when administered within the first few hours of acute myocardial infarction, to reduce infarct size is not known, although clinical studies have suggested that propranolol may be effective in reducing myocardial ischemia during acute myocardial infarction.[14,15] Gold et al[14] demonstrated that the effects of intravenous propranolol to significantly reduce ST-segment elevation and relieve chest pain were more pronounced in patients with angiographically demonstrable blood flow to the ischemic myocardium. The reduction in ST-segment elevation with propranolol appeared to be related to the presence of collateral vessels or a subtotal occlusion of the artery. These

findings are consistent with the results of the present study, in which the failure of propranolol to reduce infarct size in the baboon may have been due to the absence of a well-established collateral circulation. In addition, we found no alteration in ST-segment elevation during the 2-hour period of occlusion when comparing control and treated baboons. Hence, propranolol may only be effective in salvaging acutely ischemic myocardium if there is significant blood flow to the ischemic region.

Effects of propranolol on the oxygen supply/demand ratio: The baboon heart differs markedly from the dog heart in the degree of collateral channels available to a region of myocardial ischemia. The dog is known to have extensive subepicardial collateral channels,[16] in contrast to minimal collateralization in the baboon.[9,10] In some studies in the dog, propranolol has been shown to improve myocardial perfusion in the ischemic region.[17,18] Hence, the failure of propranolol to reduce infarct size in the present study may at least in part be attributed to an inability to significantly increase the collateral blood flow. Peter et al,[5] who reported no effect of propranolol on infarct size, could not show an improvement in myocardial blood flow within the ischemic region in their study. Becker et al[19] showed that propranolol did not increase flow to the ischemic myocardium, but did improve the endocardial-to-epicardial flow ratio. Other investigators have found that propranolol, while reducing ST-segment elevation, actually decreased myocardial blood flow to the ischemic region.[20,21] Hence the importance of propranolol in reducing infarct size or increasing collateral flow to a region of ischemia remains unclear.

In the baboon, after coronary occlusion, there is a transmural region of severe ischemia[10] that results in the absence of contraction within this ischemic segment.[9] Even though propranolol may reduce myocardial oxygen requirements in the nonischemic regions, there will be an effect on the oxygen requirements in the noncontracting ischemic segment. In contrast in the dog, because of inherent collateral blood supply, ischemia is not as severe and some tension development can occur in the ischemic region.[12] Propranolol decreases heart work and further decreases tension development in the ischemic region;[12] this may result in a reduction in infarct size by reducing myocardial oxygen requirements.

The effect of propranolol on infarct size in this study may have been in part modified by the administration of anesthetic agents. In unanesthetized dogs, propranolol may increase collateral flow to a region of ischemia,[18] an event not observed in anesthetized dogs.[5,20] However, in baboons, because of the presence of minimal collaterals, an effect on collateral flow is less likely to be an important factor. Theroux et al[22] showed a substantial increase in heart rate in the unanesthetized dog early after occlusion of the LAD, which did not occur in the anesthetized open-chested dog.[23] The effects of propranolol in decreasing heart rate are much greater in the anesthetized animal;[18] if a significant reduction in heart rate is an important factor in decreasing infarct size, it could be argued that a beneficial response may, in fact, be more likely to be observed in the anesthetized animal.

Effects of propranolol on reperfusion hemorrhage: Propranolol has been reported to decrease microvascular injury in acute myocardial ischemia in dogs.[13,24] However, this does not appear to be a primary factor in the preservation of ischemic myocardium. As pointed out by Kloner et al,[25] ultrastructural evidence of microvascular cell necrosis lags behind ultrastructural evidence of myocardial cell necrosis, suggesting that microvascular damage is not a primary cause of myocardial cell damage. Therefore, even if propranolol exerted a protective effect on the microvasculature within the ischemic region, this would not be expected to necessarily result in a reduction in infarct size. Furthermore, in the present study, there was no difference in the degree of hemorrhage within the infarct between control and treated baboons. This observation in the baboon heart is at variance with previous reports in the dog that propranolol exerts a protective effect on the microvasculature within the ischemic region.

Dosage of propranolol and hemodynamic alterations: The moderate dose of 2 mg/kg of propranolol used in this study resulted in a significant decrease in heart rate and LV contractility, with no significant change in mean arterial pressure. There was a small but significant increase in left atrial pressure, but it remained well within normal limits. These results are comparable to those found in dog studies in which identical doses were used.[1,24] Even large doses of 5 mg/kg have been well tolerated in the dog.[4,5] Most of the significant hemodynamic changes in the present study occurred after 1 mg/kg of propranolol had been administered; the addition of a further 1 mg/kg had a relatively small effect. Hence, it appears that in the baboon model, in order to produce significant hemodynamic changes, only 1 mg/kg need be administered; however, because of the relatively small effect of the second 1 mg/kg, it is unlikely this had any deleterious effect.

In conclusion, treatment with propranolol before coronary occlusion in the baboon resulted in a significant reduction in heart rate and contractility, but did not result in a reduction in the percentage of the perfusion bed of the occluded artery that underwent ultimate infarction. The absence of a well-established coronary collateral circulation in the baboon may account for the contrasting reports by some investigators on the effect of propranolol on infarct size in the dog, in which a prominent collateral circulation is usually present. Clinically, a beneficial response to propranolol may depend on the presence of significant collateral channels or subtotal occlusion of the involved artery.

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences,
The Chicago Medical School Chief, Section of Rheumatology,
V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

"This is a superb text by a sensitive, concerned, organized author of international repute. . . Each chapter is well outlined, concise, practical, and has a current and appropriate bibliography at the end. . . a skillfully structured text which is a quality contribution. . . a very readable text."
John A. Feagin, Jr., M.D.
in Military Medicine March '83

"Written in a comprehensible style, an extraordinary amount of information is compressed between hard covers. . . this book is highly recommended for physicians in training and nonrheumatologists."
Thomas G. Benedek, M.D.
in Annals of Internal Medicine, June 1983

From the Preface:

"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner. . . This text. . . is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."
Alfred Soffer, MD
Chief Editor Archives of Internal Medicine

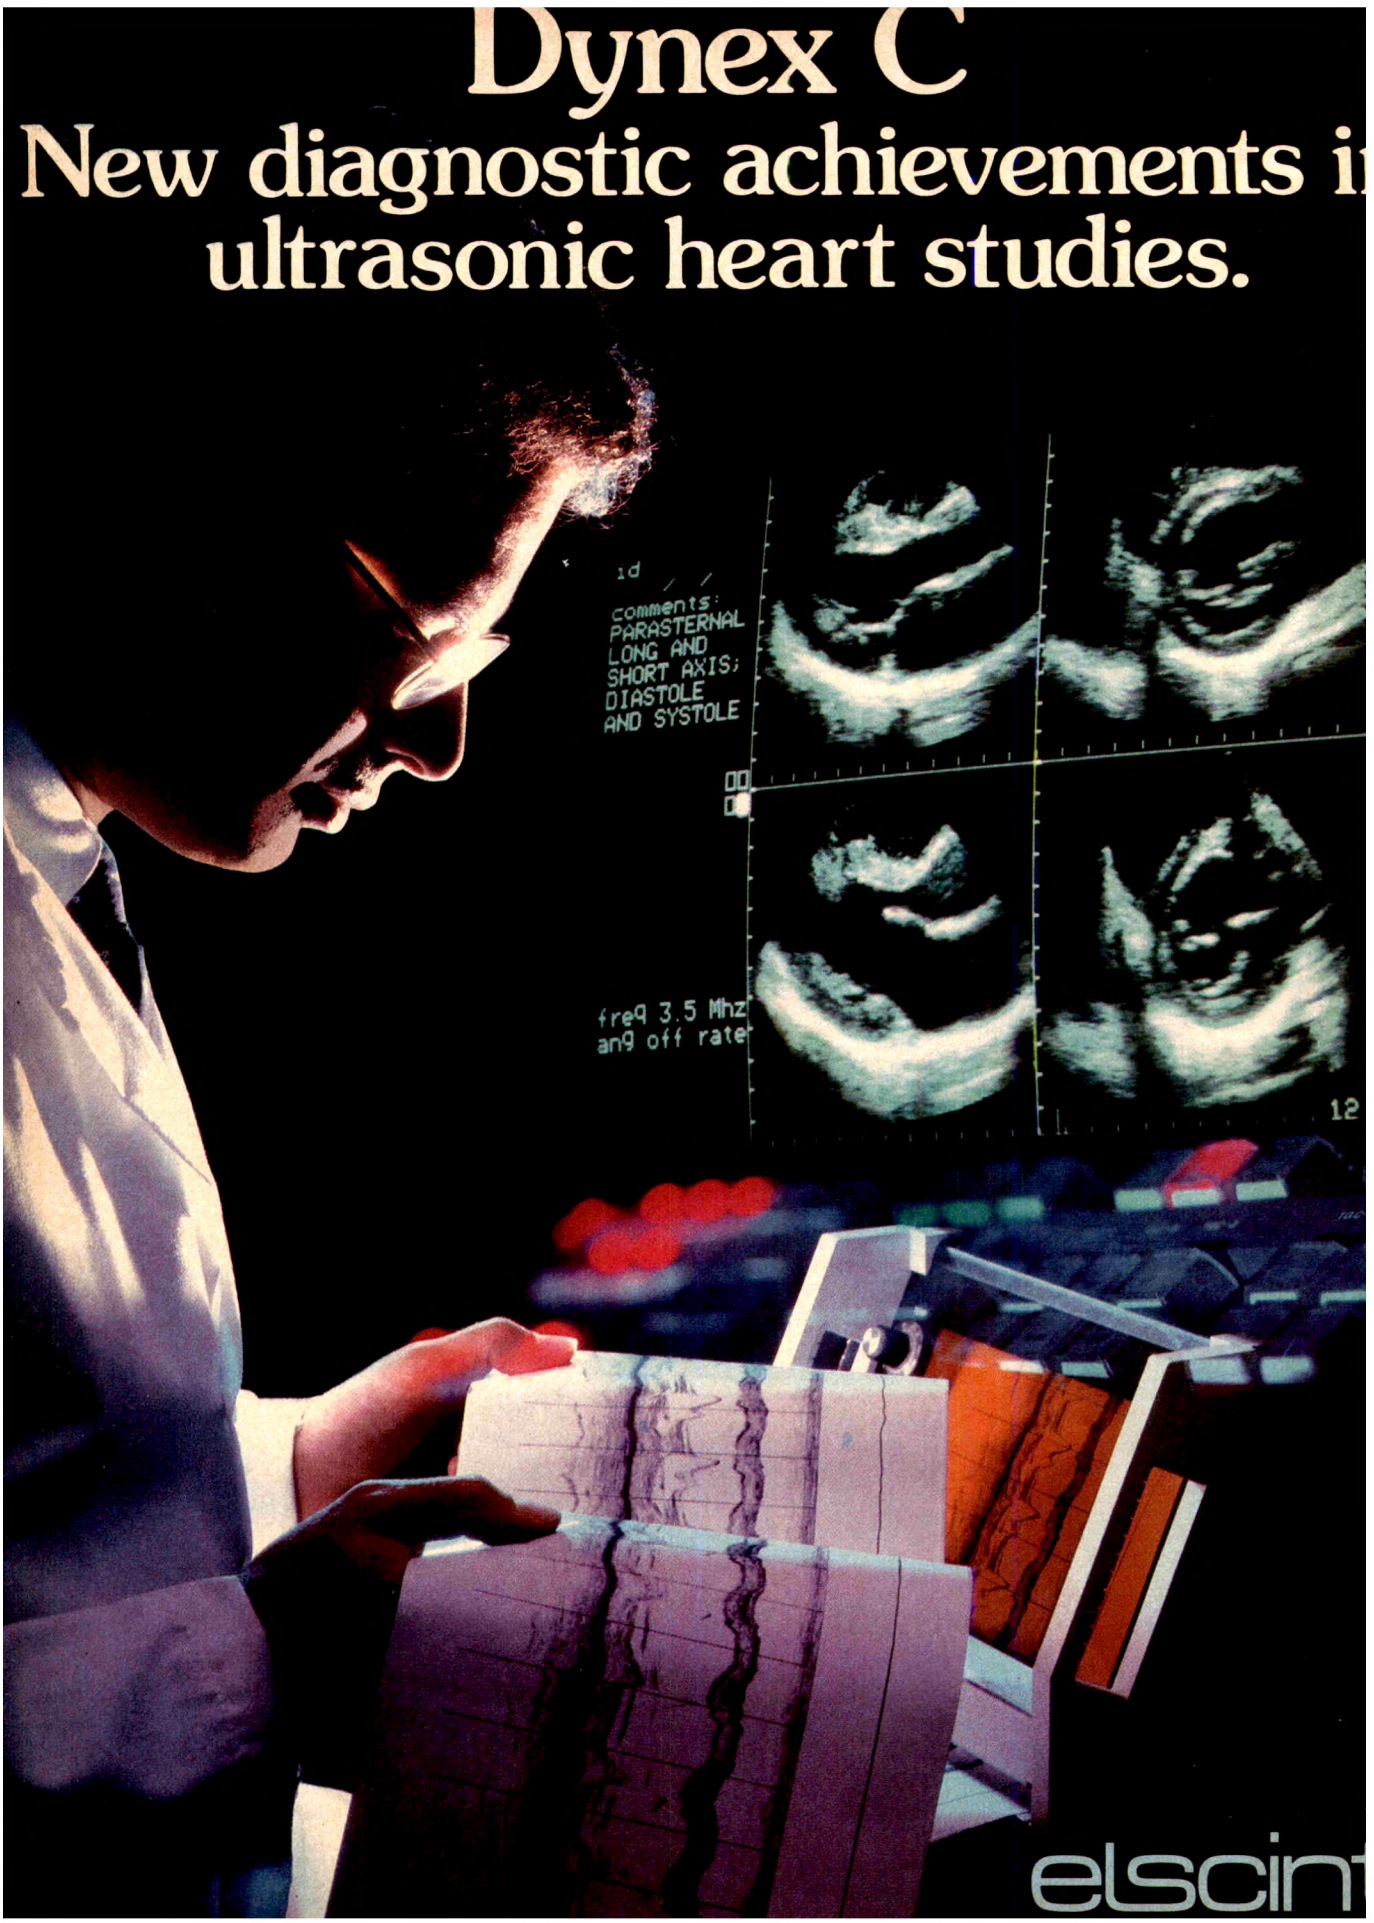
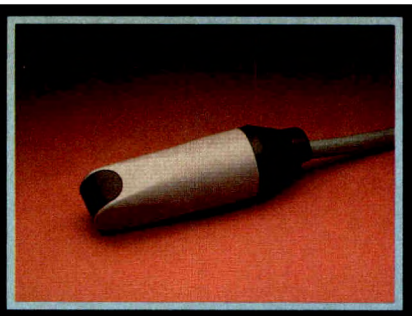
Dynex C

New diagnostic achievements i ultrasonic heart studies.



elscint

1



Dynex/C: the world's most advanced echocardiograph. With incomparable diagnostic strength deriving from the vast power of its integrated multiprocessor computer, Dynex/C has more clinical capabilities than any other echocardiograph.

1. Dynex/C Probes: Out in Front

Dynex/C 3.5 and 5 MHz mechanical sector probes, feature four unique characteristics which put them far ahead of the field:

□ Inherently fine spatial resolution due to computer controlled automatic line density optimization.

An extremely wide, continuously variable 15-105° sector angle.

□ Exceptionally fast frame rates: more than 70 frames per second, continuously variable.

□ A continuously adjustable offset angle ranging from 0-45°.

2. Multiformatting: Comparison at a Glance

2

Dynex/C's ability to display four images simultaneously gives the cardiologist an incomparable diagnostic tool. He may compare four identical views taken over a period of time, or study four different images acquired during the same examination — such as tomographic sections along the long and short axes, at end systole and end diastole.

3

3. CCRM™ — Cardiac Cycle Review Mode

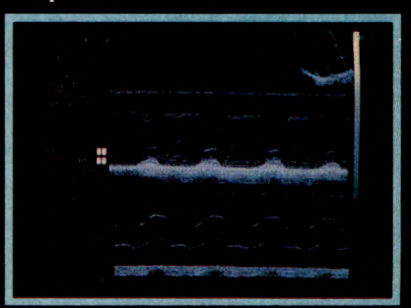
The CCRM is an exclusive Dynex/C feature for viewing fast sequential 2-D cardiac events, or a complete heart cycle. Cardiac scanning at an extremely fast frame rate stops at a pre-selected ECG point. The last 16 frames acquired are stored in memory, and may be reviewed separately or in closed-loop cine mode at a user-selected speed.

4. M-Mode Display Capabilities

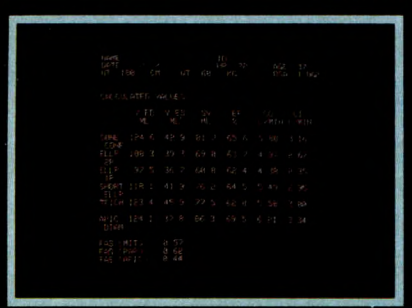
Dynex/C's M-mode has two features of truly exceptional value to the cardiologist:

1. Simultaneously with normal M-mode, Dynex/C displays a two-dimensional image with M-mode position precisely defined by a cursor.
2. *Dual M-mode:* simultaneous display of two M-modes from different cardiac regions, both synchronized with a user-selected ECG or PCG point.

4



5



5. Advanced Cardiac Data Calculations

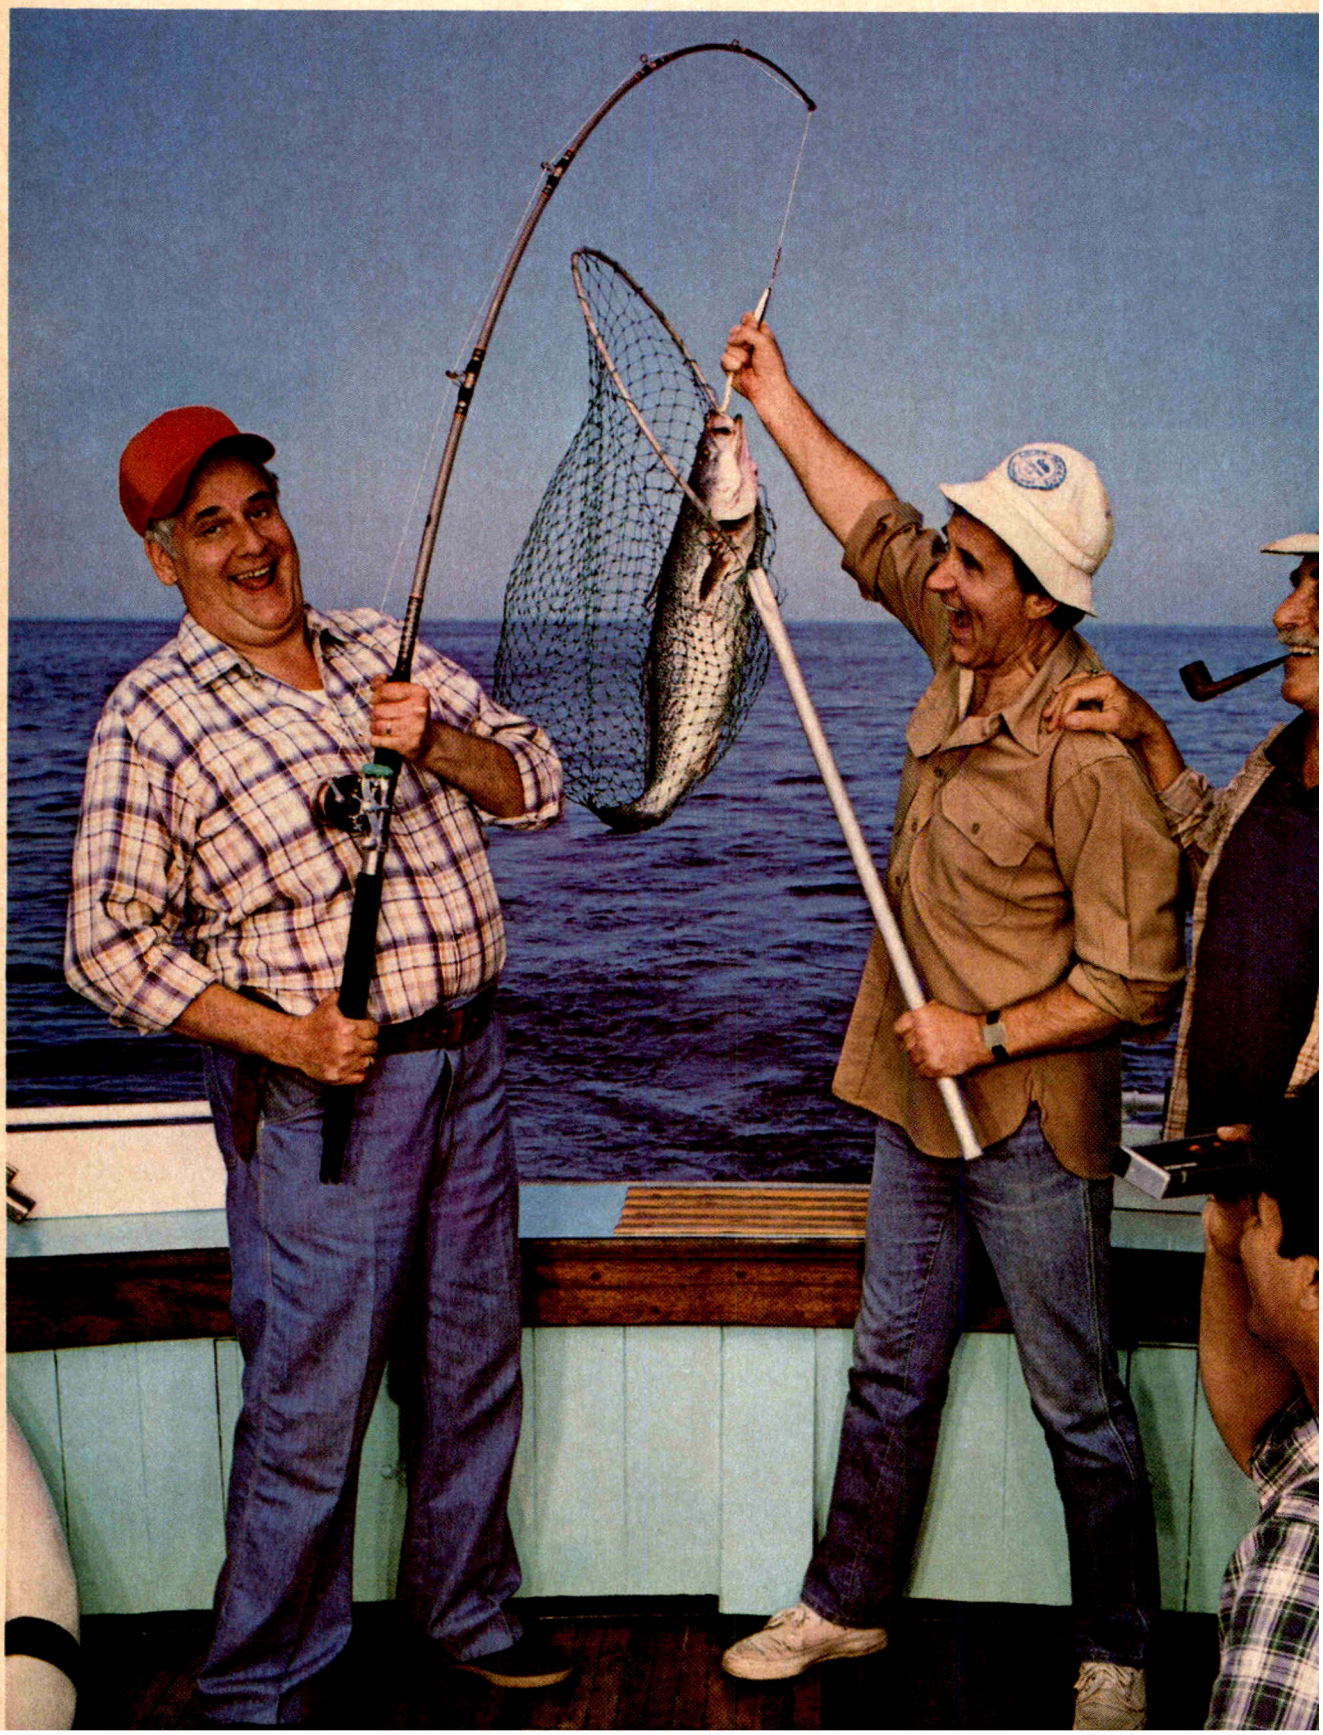
Dynex/C's comprehensive software and on-line computer enable precise measurements and calculations of vital cardiac parameters. Frozen M-mode displays give aortic and mitral valve stroke volume and flow, pre-ejection/ejection time ratio, fractional IVS shortening, and over 30 other values. Left ventricular volume is determined from 2-D images using *six* advanced calculation methods. Stroke volume, cardiac output, ejection fraction, cardiac index and more, are computed and displayed.

Dynex C: we speak from a position of strength.

Elscint European Operations

Elscint Inc., 930 Commonwealth Ave.

He can do as much or more,
with no "slowdown" from beta-adrenergic side effects.



ISOPTIN® (verapamil HCl/Knoll) IN ANGINA

It offers as much as the beta blockers. And more.

Isoptin offers clinical efficacy equal or superior to that of the beta blockers

Under the most stringent protocols (randomized, double-blind, placebo-controlled, crossover trials), Isoptin has consistently proved equal or superior to the beta blockers in antianginal efficacy.[1-8]

Isoptin offers decreased myocardial oxygen demand plus myocardial perfusion and afterload reduction, which no beta blocker can offer

Both a beta blocker and Isoptin reduce myocardial oxygen demand. But only Isoptin produces coronary and peripheral vasodilation. Therefore, with Isoptin, your patient benefits from two important additional anti-ischemic effects.

Isoptin spares patients some beta-adrenergic side effects that can compromise the quality of life

Isoptin is free of certain side effects that impair the life styles of patients on beta blockers. With Isoptin, fatigue is rare, and mental depression has not been reported. And Isoptin may be used in patients with asthma, COPD, diabetes, or peripheral vascular disease.

Cardiovascular contraindications for Isoptin and the beta blockers are similar — severe left ventricular dysfunction, hypotension (systolic pressure < 90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), and second- or third-degree AV block. The most common side effect with Isoptin (constipation occurring in about 6% of patients) can usually be corrected by diet or stool softeners.

With all that Isoptin has to offer, why not prescribe it– not after a beta blocker, but before.

Please see next page for a brief summary of prescribing information.

KNOLL PHARMACEUTICAL COMPANY
30 NORTH JEFFERSON ROAD WHIPPANY NEW JERSEY 07981
2139

ISOPTIN® TABLETS
(verapamil HCl/Knoll)
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C:* There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets. July 1982 2068

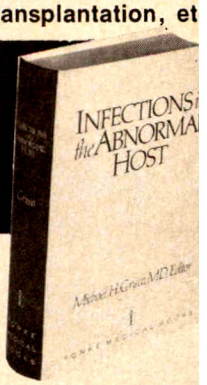
INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand diagnose, and manage the many infections which strike patient whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • Th Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Ab normalities • The Complement System in Human Disease • Structure an Function of Immunoglobulins • Human Lymphocyte Subpopulations Surface, Intracellular, Enzymatic Markers and Functions • Congenita and Acquired Primary Disorders of B and T Lymphocyte Function • Drug induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms an Relationship to Nosocomial Infections • The Effects of Malnutrition o Host Responses and the Metabolic Sequelae of Infections • Humoral an Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections Mycobacterial Infections • Viral and Chlamydial Infections • Protozoa and Helminthic Infections • Infections Complicating the Transfusion o Blood, Blood Products, Animal Exposure and Animal Products • Infec tions Complicating the Alcoholic Host • Infections in Parenteral Narcoti and Drug Abusers • Infections Complicating Uremia and Organ Trans plantation • Infections in Patients with Neoplastic Diseases • Infection Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffus Pneumonias • Host Deficiency States and Central Nervous System Infec tions • Genitourinary Infections • Infections Complicating the Rheumati Diseases • Endovascular and Prosthetic Implant Infections • Intraocula Manifestations of Systemic Infections • Selected Histopathologic Respon ses • The Microbiology Laboratory in Diagnosis and Therapy • Infection Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharma cology and Toxicity • Chemotherapy for Viral and Chlamydial Infections Chemotherapy for Protozoal and Helminthic Infections • Infection Preven tion in Patients with Cancer and Granulocytopenia • Immunologic Re constitution • Gamma Globulin and Vaccine Therapy • Index

Dose-Dependent Electrophysiologic Effects of Amiodarone in the Immature Canine Heart

ARTHUR S. PICKOFF, MD, SHARANJEET SINGH, MD, CELIA J. FLINN, MD, EDDA TORRES, MD, ALAN M. EZRIN, PhD, and HENRY GELBAND, MD,
With the technical assistance of JUDITH KASSNER *and* CARLOS A. FLORES

The electrophysiologic effects of incremental doses of intravenous amiodarone were studied in the intact neonatal canine heart and were compared with the responses observed in the adult. Seven neonatal puppies aged 5 to 14 days, and 6 adult dogs were studied. Assessment of sinus and atrioventricular (AV) nodal function and atrial and ventricular refractory periods was performed using standard His bundle recording techniques and programmed extrastimulation before and after doses of 2.5, 5 and 10 mg/kg of intravenous amiodarone. Amiodarone depressed sinus node cycle length, sinus node recovery time and AV nodal conduction in both groups. Atrial and ventricular refractory periods were also prolonged in a dose-dependent fashion in both the neonatal and adult dogs. Although similar responses to amiodarone were observed in both groups, the immature dogs were more sensitive to amiodarone in prolongation of atrial refractory periods and depression of sinus node recovery time. The neonatal group, however, demonstrated more resistance to amiodarone-induced depression of AV nodal conduction. Thus, intravenous amiodarone produces dose-dependent electrophysiologic changes in the neonate similar to those in the adult, although the significant differences in drug sensitivity may be clinically important.

(Am J Cardiol 1983;52:621–625)

Amiodarone has been proved effective in a wide variety of atrial and ventricular arrhythmias in adults.[1–5] In children, this benzofuran derivative has been reported to be well tolerated and also very effective in treating cardiac arrhythmias.[6] Recent reports have suggested that in children, amiodarone may be particularly useful in treating atrial flutter[7] and primary ventricular arrhythmias.[8] However, the electrophysiologic effects of amiodarone in the immature heart have not been defined. Information available concerning the electrophysiologic effects of intravenous amiodarone has been from studies performed in the adult. In these studies, intravenous amiodarone has been shown to prolong atrioventricular (AV) nodal conduction time (that is, prolonged AH interval), although the effects on sinus node recovery time and atrial and ventricular refractory periods have been variable.[9–13] The objective of this study is to define the electrophysiologic responses of the immature mammalian heart to incremental intravenous doses of amiodarone. These responses are compared with those observed in a group of mature animals to define developmentally determined differences in the response to amiodarone of the neonatal myocardium and specialized conduction system.

From the Division of Pediatric Cardiology, Department of Pediatrics, University of Miami School of Medicine, Miami, Florida. This study was supported in part by Clinical Investigator Award HL00881, and Research Training Grant HL07436 from the National Heart, Lung, and Blood Institute, the National Institutes of Health, Bethesda, Maryland, and by a grant from the American Heart Association of Greater Miami. Manuscript received March 14, 1983; revised manuscript received May 9, 1983, accepted May 10, 1983.

Methods

Two groups of dogs were studied: Group I included 7 neonates, aged 5 to 14 days, and Group II included 6 adults. All subjects were anesthetized with pentobarbital, 20 to 30 mg/kg, either intravenously (Group II) or intraperitoneally (Group I). All subjects underwent endotrachial intubation and were placed on an artificial ventilator with a tidal volume of 7 to 15 ml/kg.

Surface electrocardiographic lead II and right femoral artery blood pressure were monitored. Through a femoral transvenous cutdown, a No. 5 Elecath quadripolar electrical catheter (or No. 4 tripolar catheter in the neonates) was positioned under fluoroscopic visual guidance to the high right atrium to record the atrial electrogram and pacing. Through a left femoral approach in Group II or an external jugular vein approach in Group I, No. 5 tetrapolar and No. 4 tripolar electrophysiologic catheters, respectively, were advanced to the right ventricle apex. The His bundle electrogram was recorded by introducing a No. 4 tripolar catheter into the right carotid artery and advancing the catheter to the right coronary cusp of the aorta. All intracardiac electrograms were amplified at a filter setting of 40 to 500 Hz (Electronics for Medicine DR-6) and recorded simultaneously with the surface electrocardiogram and femoral artery blood pressure on direct-writing paper (Kodak linagraph paper 2201, Eastman Kodak Company) at a paper speed of 100 mm/s.

All data are expressed in milliseconds (except %SNRT), mean ± standard error.
* Significant difference ($p < 0.05$), neonate versus adult.
† Significant dose-related increase ($p < 0.05$).
ATERP = atrial effective refractory period; ATFRP = atrial functional refractory period; CSNRT = corrected sinus node recovery time; %SNRT = percent sinus node recovery time; VERP = ventricular effective refractory period; VFRP = ventricular functional refractory period.

Rapid atrial pacing, programmed atrial extrastimulation and programmed ventricular extrastimulation tests were performed in all dogs. Rapid atrial pacing was performed at rates of 200 to 400 beats/min (that is, paced cycle lengths of 300 to 150 ms) at 50-beats/min increments until Wenckebach periodicity was recorded. Atrial and ventricular extrastimulation tests were performed coupled to an identical fixed paced cycle length in each dog. The mean paced cycle length for performing extrastimulation tests in the neonatal group was 251 ms and in the adult group, 359 ms. The basic driving rhythm and extrastimuli were delivered by a programmable digital stimulator (Medtronics model 5325). Atrial and ventricular extrastimuli were coupled to the eighth paced beat and delivered at 10-ms decrements until either atrial or ventricular refractoriness was reached. Stimuli were delivered bipolar, at twice threshold and with a pulse duration of 2 ms.

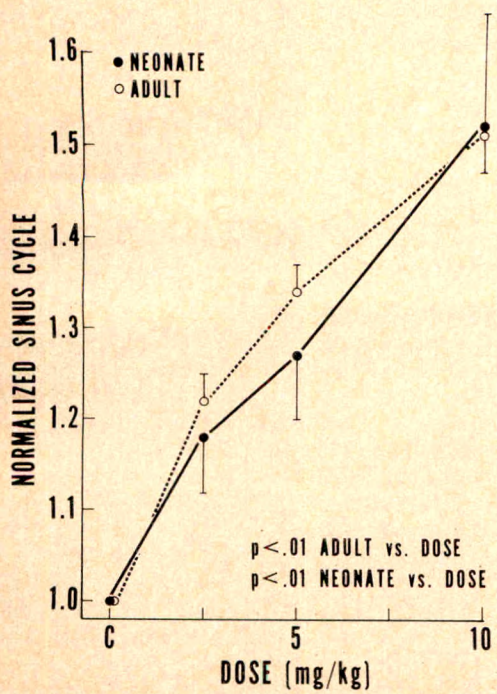

FIGURE 1. The normalized change in sinus cycle length plotted as a function of cumulative amiodarone dose. For both the neonate and the adult, a significant and similar dose-dependent increase occurs.

In this report, S_1, A_1, H_1 and V_1 refer to the pacing spike artifact, atrial, His bundle and ventricular electrogram of the basic paced rhythm, and S_2, A_2, H_2 and V_2 refer to corresponding events recorded with the extrastimulus. Electrophysiologic measurements were performed according to standard definitions[14] and are summarized as follows: effective refractory period of the atrium = the longest S_1S_2 that fails to result in atrial depolarization; functional refractory period of the atrium = the shortest A_1A_2 in response to any S_1S_2; effective refractory period of the ventricle = the longest S_1S_2 that fails to produce a V_2; functional refractory period of the ventricle = the shortest V_1V_2 in response to any S_1S_2 interval.

The percent sinus node recovery time (%SNRT) and corrected sinus node recovery time (CSNRT) were calculated according to standard methods[14] after rapid atrial pacing for 30 seconds at progressively higher rates (200 to 400 beats/min at 50-beat/min increments).

In each dog, the complete electrophysiologic protocol (which was usually completed in 20 to 30 minutes) was performed before drug administration and served as the control study. This formed the basis of assessing the effects of amiodarone. After completing the control study, 2.5 mg/kg of amiodarone hydrochloride (Labaz Laboratories) diluted in sterile water was administered intravenously. After 10 minutes to allow for drug distribution, the entire electrophysiologic protocol was repeated. After completing this study, and at a time not to exceed 45 minutes after the preceding dose, a second 2.5-mg/kg dose was administered (cumulative 5 mg/kg) and the protocol was repeated. Finally, a 5-mg/kg dose was administered (cumulative dose 10 mg/kg) and a complete electrophysiologic assessment was performed.

Statistical analyses of the effects of dose on a given electrophysiologic parameter in each age group was performed by an analysis of variance. Comparisons of paired data between adult and neonatal groups at specific dosage levels was performed by a Student t test. In all statistical analyses, a p value <0.05 was required to indicate significance. Data used to compare the electrophysiologic responses of the adult and neonate are normalized to account for inherent differences in heart rate and refractoriness: normalized value = observed value/control value.

Results (Table I)

Sinus cycle length and sinus node recovery time: In both the neonatal and adult groups, amiodarone produced significant dose-dependent changes in the sinus cycle length (Fig. 1). In the adult group, an overall increase in sinus cycle length of 51% was observed across the entire dosing interval. In the neonate, a clear dose-dependent increase of sinus cycle length was observed (274 ± 7 ms control to 410 ± 33 ms); this was, on a percentage basis (52%), comparable to that in the adult.

Changes in %SNRT were small in both the adult and neonatal groups (Fig. 2), which reflects primarily the proportional prolongation of SNRT and sinus cycle length by amiodarone. The depressant effects of amiodarone on sinus node function was better observed by considering the CSNRT (Fig. 2). In the neonate, a dose-dependent increase in CSNRT was observed, with an overall mean increase of 115 ± 37%. Sinus node function in the neonates as measured by CNSRT tended to show more depression with amiodarone than that in the adult (normalized CSNRT—1.78 ± 0.17 neonate, 1.13 ± 0.14 adult at 5-mg/kg dose level; $p < 0.02$).

Resting His intervals and atrioventricular nodal function: No significant changes in either the PA or the HV intervals were observed in either the neonatal or adult groups over the entire dosing protocol (Table I). However, as reported in other studies, amiodarone produced a significant change in AV nodal conduction in the adult as measured by both the resting AH interval and the paced cycle length at which AV nodal Wenckebach periodicity was observed.

In the adult group, the AH interval was prolonged by 42% over the dosage range and the paced cycle length at which Wenckebach was observed in the AV node increased by 49% (Fig. 3 and 4). In the neonate, a mean increase was observed in the resting AH interval of only 16% over the entire dosing range and of only 34% in the paced cycle length resulting in AV nodal Wenckebach (Fig. 3 and 4). Thus, conduction through the AV node appeared to be depressed to a lesser extent by amiodarone in the neonate than in the adult.

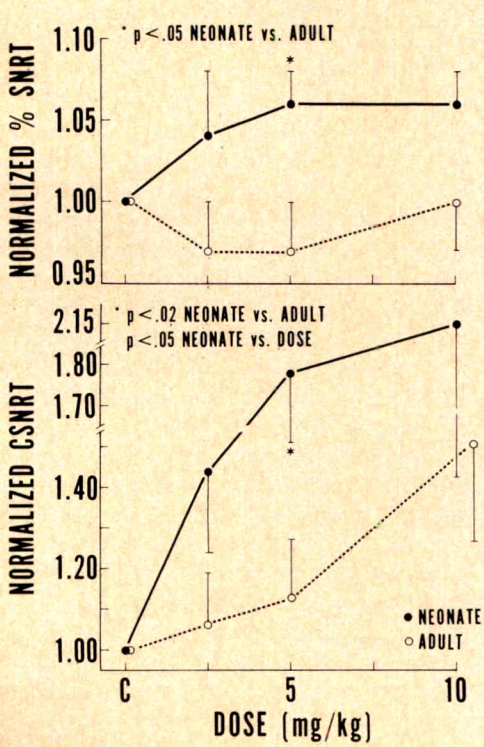

FIGURE 2. The normalized percent sinus node recovery time (% SNRT) and corrected sinus node recovery time (CSNRT) plotted as a function of amiodarone dose. Although no clear dose-dependent increase in % SNRT is evident, the CSNRT increases significantly in the neonate

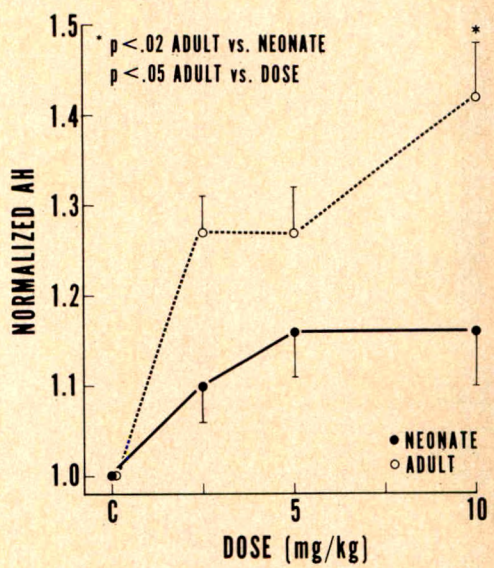

FIGURE 3. Normalized change in AH interval plotted as a function of amiodarone dose for the neonate and adult. The AH interval in the adult is prolonged to a greater degree than in the neonate.

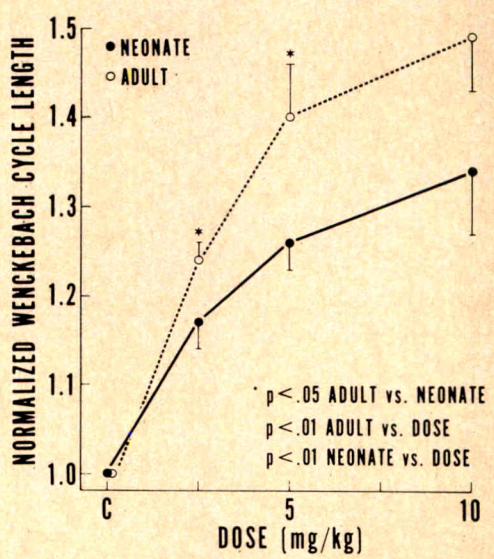

FIGURE 4. Normalized paced cycle length resulting in Wenckebach periodicity in the neonate and adult groups plotted as a function of amiodarone dose. As shown for the AH interval, atrioventricular nodal conduction is more significantly depressed by amiodarone in the adult

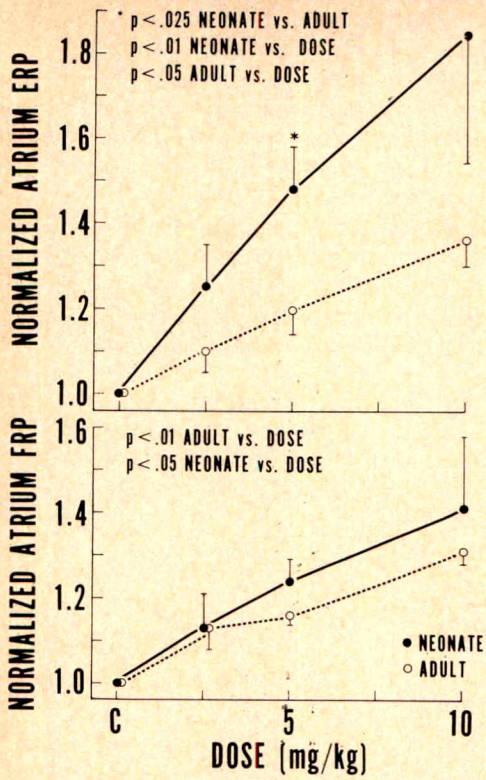

FIGURE 5. Normalized atrial effective refractory period (ERP) and atrial functional refractory period (FRP) plotted against amiodarone dose. Dose-dependent increases occur in both the neonatal and the adult group. The neonatal atrium appears to be more sensitive than the adult atrium to amiodarone.

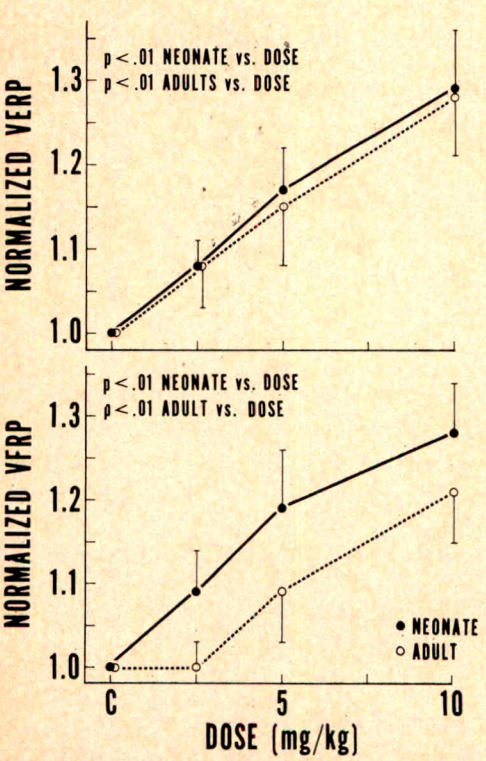

FIGURE 6. Normalized ventricular effective and functional refractory periods (VERP and VFRP) versus amiodarone dose. Similar dose-dependent increases occur in the neonatal and the adult group.

Atrial refractory periods: Amiodarone produced dose-dependent increases in both the atrial effective and functional refractory periods in the adult and neonatal groups (Fig. 5). Amiodarone appeared to prolong the atrial refractory periods (particularly the effective refractory period) to a significantly greater degree in the neonatal group. Thus, the 35% change in the atrial effective refractory period in the adult produced by the highest amiodarone dose would be achieved in the neonate at a much lower dose of 2.5 to 5 mg/kg (Fig. 5). Similarly, the changes in the functional refractory period of the atrium tended to be greater in the neonatal group than in the adult group (1.41 ± 0.17 in the neonate versus 1.31 ± 0.03 in the adult). Thus, the neonatal atrium was apparently more sensitive (that is, a greater percent change in refractory periods) than the adult to intravenous amiodarone.

Ventricular refractory periods: Ventricular refractory periods increased in a dose-dependent fashion in both the neonatal and adult groups (Fig. 6). The effective refractory period increased a mean of 29% in the adult and 28% in the neonatal group over the entire dosage range, and the functional refractory periods increased in parallel and to a similar degree (28% in the adult and 21% in the neonate). Thus, amiodarone appeared to be equipotent in both groups in prolongation of ventricular refractory periods.

Discussion

In this study, we have defined the electrophysiologic effects of intravenous amiodarone in the intact immature mammalian heart. Our data demonstrate that amiodarone produces significant dose-dependent increases in sinus cycle length, CSNRT, and atrial and ventricular refractory periods. Amiodarone also produces dose-dependent suppression of AV nodal conduction in the immature heart, but this suppression is primarily evident only when the AV node is "stressed" by rapid atrial pacing. These observations in the neonate are similar to the electrophysiologic dose-response curves in the adult dog in the present study and in that of Jaillon et al[9] (Table II). In humans, however, although AV nodal depression has been uniformly reported after amiodarone administration, changes in sinus rate and atrial and ventricular refractory periods have been variable. Although this may in part be explained by species differences, differences in autonomic tone or differences in methods of sedation for electrophysiologic study, we believe that some of these discrepancies may be related to the fact that in human subjects, only single-dose studies have been performed to assess the electrophysiologic effects of amiodarone. To completely characterize an agent's electrophysiologic responses, multidose studies are more likely to reveal information concerning the effects of a given drug.

Of particular interest to the pediatric cardiologist is the relative responsiveness of the immature myocardium to antiarrhythmic agents. Both clinical and microelectrode studies provide convincing evidence that important quantitative differences exist in the re-

sponses of the immature mammalian heart to various antiarrhythmic drugs and that both increased sensitivity and decreased sensitivity can be found.[15–18] In the present study, amiodarone had measurable age-related differences in its effect upon CSNRT, atrial refractoriness and AV nodal conduction. Concerning the sinus node, although the sinus cycle length is prolonged in both the adult and neonate to a similar extent by amiodarone, sinus node function as measured by CSNRT is prolonged more by amiodarone in the neonate. We have also found that the neonatal atrium appears to be more sensitive (that is, a greater percent increase in refractory periods) than the adult atrium to amiodarone.

In contrast to the increased sensitivity of the neonatal sinus node and atrium, this study indicates that amiodarone-induced depression of AV nodal conduction is more marked in the adult than in the neonate. Thus, higher doses of amiodarone may be required in the neonate to produce a degree of change in AV nodal conduction similar to that in the adult.

Whether the differences we observed in the responses of the neonate and adult to amiodarone reflect changes with age in the status of the autonomic nervous system, inherent differences in the ionic mechanisms responsible for the generation of the neonatal action potential, or other undetermined factors is not addressed by this study. Furthermore, we do not know how the results of this study would be altered if diseased hearts (instead of normal hearts) had been studied. Nevertheless, this report suggests that important differences may exist in the manner in which the immature heart responds to intravenous amiodarone. These differences may prove to be of clinical importance in the formulation of a rational approach to amiodarone therapy in the immature human being.

Protection of Turkeys Against Furazolidone-Induced Cardiomyopathy

JUDITH K. GWATHMEY, VMD and ROBERT L. HAMLIN, DVM, PhD

When fed furazolidone, 700 ppm, with their mash, most turkey poults develop dilated cardiomyopathy characterized by gross left ventricular dilatation with thinning of both the left ventricular free wall and ventricular septum. Birds fed propranolol, but not digoxin, did not develop this cardiomyopathy. It is not known what pharmacologic property of propranolol conferred protection or if mammals would receive similar protection.

(Am J Cardiol 1983;52:626–628)

Turkey poults fed 700 ppm of furazolidone develop dilated cardiomyopathy (DC) within 2 weeks.[1–3] Because turkey poults develop DC spontaneously,[4] it is not known whether furazolidone produces DC or merely potentiates it. DC in turkeys is characterized by ventricular dilatation, premature death and ascites. The clinical findings mimic quite closely those in mammals with DC.

How furazolidone produces cardiomyopathy in turkeys is unknown; however, certain biochemical observations suggest that the compound may inhibit the conversion of pyruvate to acetyl coenzyme A.[5] Studies by others have shown elevation of both lactate and pyruvate in turkeys treated with furazolidone. Further, significant increases in myocardial glycogen levels in both furazolidone-induced cardiomyopathy and spontaneous round heart disease have been observed. Enzyme inhibition of the glycogen metabolic pathway by furazolidone raises the possibility that the spontaneous heart condition that resembles furazolidone-induced cardiomyopathy represents a manifestation of glycogen storage disease. Abnormal accumulation of glycogen in heart and skeletal muscle is similar to that reported in sheep and dog with idiopathic glycogenolysis. In these cases, as in Pompe's disease in man, an enlarged heart was a characteristic finding. Other similarities include a familial occurrence, early onset in life, anorexia, cyanosis, dyspnea, failure to grow and a tendency toward sudden death when an affected animal is stressed.[5] Morphologic alterations such as loss and disarray of myofilaments, accumulation of cytoplasmic glycogen and mitochondrial changes observed in the drug-induced cardiomyopathy in turkey poults are similar to those in a number of mammalian species.[2,5]

Prophylaxis against or therapy for DC is sought because of the prevalence and catastrophic consequences; beta-adrenergic blocking agents and digitalis have been proposed for both.[6] The purpose of this study was to determine if propranolol or digitalis protects turkey poults against the development of DC when fed furazolidone.

Methods

Ninety 7-day-old broad-breasted white turkey poults were separated into 6 groups of 15 turkeys per group. One group received only a commercial mash and served as a control, and other groups received, in addition, 1 of the following: (1) furazolidone, 700 ppm, ad libitum in commercial mash; (2) furazolidone (as in 1) plus digoxin* orally, 0.0025 mg/100 g, daily; (3) furazolidone (as in 1) plus propranolol* orally, 1 mg/100 g, 3 times a day; (4) propranolol; and (5) digitalis.

The turkeys were fed the above for 2 weeks, after which they were killed. Body weights and heart weights were measured to permit calculation of heart weight:body weight ratios. After hearts were fixed in formalin for 3 weeks, median sagittal sections were cut through them and the sections were photographed and amplified equally. Hearts fixed for >3 months return to a volume nearly identical to that immediately after death.[7] From the photographs, the following measurements were made at right angles to the long axis of the heart and midway between the apex and base: left ventricular (LV) free-wall thickness; LV luminal diameter; LV luminal length; and ventricular septal thickness.

Means for each variable for each group were calculated, and when indicated by a suitable F statistic (analysis of variance),

they were compared by Newman-Keul's, with $p < 0.05$ considered significantly different.

Results

All turkeys survived the 2-week feeding. Figure 1 shows hearts typical of all groups. Turkeys that received furazolidone and furazolidone plus digitalis—but no others—showed remarkable dilatation of the left ventricle and thinning of the LV free wall and ventricular septum. Hearts from these turkeys occupied the greater portion of the thorax at postmortem examination.

Table I shows means for all variables measured. For each variable, means for turkeys that received either furazolidone or furazolidone plus digitalis did not differ between these 2 groups. For each variable, means from the first cluster (of 2) were different from means of the second cluster (of 4). Thus, furazolidone produced remarkable LV dilatation, neither digitalis nor propranolol alone caused any change, and propranolol prevented but digitalis did not prevent the dilatation when fed with a dose of furazolidone that produces this cardiomyopathy.

Discussion

This study shows that propranolol, but not digitalis, prevents LV dilatation and free wall thinning produced by furazolidone in turkey poults. We do not know if the mechanism by which furazolidone produces cardiomyopathy is analogous to that by which birds develop the disease spontaneously or, even if the mechanisms were identical, whether propranolol would deter or completely block the development in mammals.

Furthermore, propranolol possesses many properties (for example, beta blockade, platelet inhibition, calcium-channel blockade and membrane stabilization), so we do not know what property of this compound prevents ventricular dilatation.

Swedberg,[6] Waagstein,[8] and their co-workers showed that reduction of beta-adrenergic drive prolonged the lives of human patients with dilated cardiomyopathy. The survival rate in 24 patients with severe failure was 83, 66 and 52% after 1, 2 and 3 years, respectively. In a comparable group of patients who were treated without beta blockers, the survival rate was 46, 19 and 10%. They

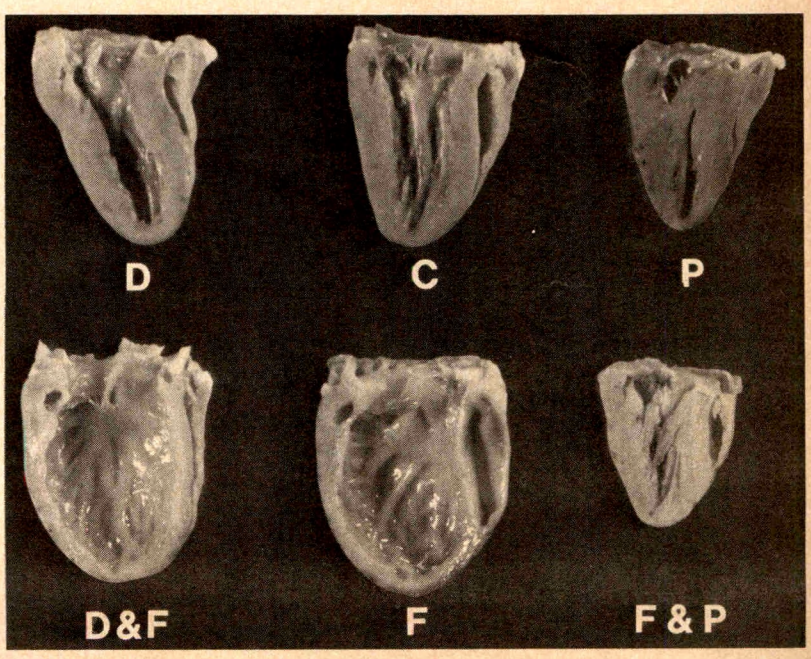

FIGURE 1. Hearts from each of the 6 treatment groups. **Top,** hearts from digoxin (D)-, control (C)- and propranolol (P)- treated turkeys. **Bottom,** hearts from turkeys that received digoxin plus furazolidone (D & F), furazolidone (F), and furazolidone plus propranolol. (F & P).

demonstrated objective indications of improved LV function and less ventricular dilatation. Findings indicated a decrease in LV end-diastolic diameter, an increase in ejection fraction and an increase in LV ejection time indicating an increased stroke volume. Therefore, improved myocardial function with chronic beta blockade could improve prognosis. They suggested that reduction in heart rate by partial beta blockade—similar to what results from bedrest—may be a partial explanation for the beneficial effects of propranolol. It was also found that withdrawal of treatment caused a deterioration of myocardial function and, in several patients, led to distinct exacerbation of their symptoms.[9]

Thus, cardiac deterioration may result primarily from a primary insult (for example, viremia, adriamycin, alcohol or cobalt) and secondarily from excessive drive by catecholamines, and the reduction in beta-adrenergic drive by blocking agents may save the heart from the adversity of excessive adrenergic drive.

Bristow et al[10] reported that beta-receptor density is reduced greatly in failing human hearts and that these hearts are less responsive to catecholamines. Motulsky and Inset[11] proposed that the reduced beta-receptor activity may have resulted from sustained elevation of catecholamines. Thus, since propranolol should abolish or reduce the effects of elevated catecholamines, population of beta-adrenergic receptors may not be reduced, and potential for changes in myocardial contractility mediated by beta receptors may not be abolished.

Mechanism of Calcification of Porcine Bioprosthetic Aortic Valve Cusps: Role of T-Lymphocytes

ROBERT J. LEVY, MD, FREDERICK J. SCHOEN, MD, PhD, and SUSAN L. HOWARD, BS

Calcification of glutaraldehyde-preserved porcine aortic valve bioprosthetic cusps limits their success as cardiac valve substitutes. Subcutaneous implants of porcine bioprostheses in rats and rabbits have provided a convenient experimental tool to study this calcification process. Previous clinical research has suggested that the host's immune response to the porcine xenograft tissue may contribute to the calcific degeneration. To investigate the possible contribution of the immune response, porcine bioprosthetic cusps implanted subcutaneously in congenitally athymic (nude) BALBc mice and normal controls were analyzed biochemically and histologically after retrieval at 21 days. Calcification was comparable in implants retrieved from athymic (calcium 95.5 ± 24.5 μg/mg) and normal mice (calcium 102.3 ± 4.66 μg/mg). Explants from nude mice demonstrated fewer adherent cells than those from normal animals, but the morphologic characteristics of the calcification were the same in both groups, with dystrophic mineralization of the spongiosa predominating. Thus, normal T-lymphocyte function is not necessary for porcine bioprosthetic calcification, and immunologic processes do not contribute to this process.

(Am J Cardiol 1983;52:629–631)

Bioprosthetic cardiac valves fabricated from glutaraldehyde-preserved porcine aortic valve xenografts are widely used for cardiac valve replacement.[1–5] Late calcification of porcine bioprostheses frequently leads to their failure due to cuspal stiffening or tearing.[6–8] The host's immune response to the xenograft tissue has been considered by some investigators to play a role in the pathogenesis of the calcification.[9–11] Calcification of porcine bioprotheses has been studied by implanting porcine aortic valve cusps subcutaneously in rabbits[12] and rats.[13] After several weeks in rats[13] and several months in rabbits,[12] experimental implants demonstrate morphologic and biochemical abnormalities similar to those implanted in the heart.[12,13]

Nude mice are congenitally athymic and have a grossly defective immune system due to deficiencies in T-cell–dependent immunologic processes. These mice have a virtual absence of T-lymphocytes[14,15] and therefore lack T-cell effector functions, including delayed hypersensitivity and rejection and facilitation of antibody formation. In the present study, the hypothesis that T-lymphocytes may play a role in calcification of porcine bioprostheses was examined by comparing subcutaneous porcine bioprosthetic cusps implanted in congenitally athymic (nude) mice with those implanted in normal mice.

Methods

Porcine bioprosthetic cusps were prepared according to the methods of Carpentier et al,[1] and were stored at room temperature in 0.2% glutaraldehyde solution, buffered to pH 7.4 in 0.05 *M* $Na_2H_2PO_4$, 0.9% NaCl. Three-week-old male BALBc nude mice and normal BALBc male mice obtained from Charles River Laboratories received subcutaneous implants according to established techniques.[12,13] The mice were maintained in laminar flow enclosures with filter-capped cages. Drinking water was passed through Millipore filters, and lab chow (Ralston-Purina) feedings were autoclaved. No mice had overt infections during the course of the experiments. Twenty-one days after implantation, blood sampling was done by cardiac puncture. The mice were then killed and the valve cusps retrieved.

A portion of each cusp was immediately fixed in 0.1 *M* cacodylate-buffered (pH 7.4) 2.5% glutaraldehyde, 2% paraformaldehyde solution. Histologic specimens were subsequently dehydrated in graded alcohols, embedded in glycolmethacrylate medium (JB-4, Polysciences), sectioned at 2 to 3 μm and stained with hematoxylin-eosin for general mor-

phology and by von Kossa's method for calcium-phosphate. Cell attachment to the surface of the retrieved bioprosthetic leaflets was assessed semiquantitatively as none (0), rare (1+), few (2+) or many (3+). Retrieved leaflets were milled under liquid nitrogen to a coarse powder and dried to constant weight in a vacuum dessicator. Then, 6 N-HCl hydrolysates of bioprosthetic specimens were analyzed for calcium levels by atomic absorption,[12] and for phosphorus levels by the method of Chen et al.[16] Calcium and phosphorus levels were also quantitated in the mouse serums using the same methods. Data were assessed statistically using a Student t test.

Results

The bioprosthetic cusps retrieved from both athymic and normal mice were grossly thickened and calcified to a similar degree. Microscopic calcification was similar morphologically in the bioprosthetic cusps from the nude and normal mice (Fig. 1). By light microscopy, there was a diffuse pattern of calcific deposits, ranging from 5 to 50 μm, many of which were clearly associated with residual, devitalized porcine valve nuclei. No host cell penetration was noted. Although retrievals from normal mice had adherent cells (principally macrophages) ranging from rare to many, there was markedly diminished cellular adherence to the porcine bioprosthetic tissue in the nude mouse explants with none to rare cells attached (Fig. 1).

Biochemical analyses of porcine bioprosthetic cusp retrievals (Table I) revealed increased calcium and phosphorous content in those retrieved from both nude and normal mice compared with the unimplanted bioprosthetic cusps. No statistically significant differences were noted in valvular calcium and phosphorus content between porcine bioprosthetic cusps retrieved from athymic and those from normal mice. Serum calcium and phosphorus levels were also not significantly different between the 2 groups.

Discussion

Calcification of glutaraldehyde-preserved porcine aortic valve cusps, previously studied subcutaneously in rabbits[12] and rats,[13] has morphologic and biochemical features analogous to those seen in clinical explants

TABLE I Xenograft Valve Nude Mouse Studies

after several years.[17] Experimental degenerative calcification of porcine bioprosthetic cusps is dependent on the glutaraldehyde pretreatment of the valve cusps, is more severe in younger animals and is apparently independent of host inflammatory cell attachment.[13] The present study indicates that subcutaneous calcification of porcine bioprosthetic cusps also occurs in the mouse, which has a morphology and biochemistry similar to that previously observed both clinically and experimentally.

The primary result of this study is that calcification of porcine bioprosthetic cusps was identical in congenitally athymic (nude) mice and controls. A role of the immune response in porcine bioprosthetic calcification has been previously suggested. Several cases of porcine bioprosthetic xenograft valve failure associated with immunologic rejection have been reported.[10,11] Rocchini et al[9] demonstrated both a humoral and cellular immune response to porcine xenograft valve replacements in a large clinical series, including several cases of calcification. A number of the cases reported by Rocchini et al[9] had plasma hypergammaglobulinemia and plasmacytosis. Porcine bioprosthetic immune complex deposition and cellular infiltration with lymphocytes and macrophages were also described. Although it is not clear whether the immune processes were primary or secondary, these investigators proposed a mechanism whereby bioprosthetic tissue damage secondary to the immune response may lead to valvular calcification. Experimental induction of both humoral[18] and cellular[19] immune responses elicited to subcutaneous porcine bioprosthetic implants has been observed by Bajpai and his co-workers. Neither of these studies, however, specifically examined whether the immune response to the porcine bioprosthetic xenografts had a cause-and-effect relationship to the calcification.

Our results show that experimental calcification of porcine bioprosthetic xenograft tissue does not require normal T-lymphocyte activity, and suggest that calcification is not caused by immunologic phenomena. However, the results of the present study do not eliminate the possibility that immunologic reactions to the xenograft tissue may be of pathogenetic importance to the ubiquitous collagen deterioration and degenerative processes other than calcification in long-term porcine bioprosthetic circulatory implants.[6–8]

Formation of Cartilage in Bioprosthetic Cardiac Valves Implanted in Sheep: A Morphologic Study

ELOISA ARBUSTINI, MD, MICHAEL JONES, MD, and VICTOR J. FERRANS, MD, PhD

Foci of cartilage were found in 12 of 120 bioprostheses implanted in young sheep for 13 to 24 weeks, but in none of 47 bioprostheses implanted for <13 weeks. Cartilage was found more frequently ($p < 0.01$) in bioprotheses implanted in the tricuspid position than in those implanted in the mitral position. In porcine aortic valvular bioprostheses, the cartilage was preferentially localized in the region of the muscle shelf; in pericardial bioprostheses, it occurred in the fibrous sheaths covering the cusps. In both instances, the cartilage was found to undergo calcification and was considered to be formed by metaplasia of connective tissue cells of host origin. **(Am J Cardiol 1983;52:632–636)**

Although many pathologic conditions, such as infection, fibrous sheathing, thrombosis and tissue degeneration, can be responsible for dysfunction of cardiac valvular bioprostheses, mineralization of connective tissue represents the most common cause of bioprosthetic dysfunction.[1,2] Cellular mechanisms of calcification have been previously considered not involved in the formation of calcific deposits in bioprosthetic cuspal tissue because the native cells of bioprosthetic valves are killed by the commercial preimplantation process with glutaraldehyde.[3] In addition, connective tissue cells of host origin have not been found to participate in the calcification of bioprosthetic connective tissue. Nevertheless, we recently found nodules of calcifying hyaline cartilage in cusps of porcine aortic valvular bioprostheses and bovine pericardial bioprostheses explanted from experimental animals. This report describes the incidence, location and morphology of these nodules, and proposes an additional mechanism for the process of mineralization of bioprostheses.

Methods

The study material consisted of 167 bioprostheses (Table I) recovered after implantation in young sheep, either in the tricuspid or in the mitral position, according to procedures previously described.[4] The explants were considered to be early if the bioprostheses had been in place for <6 weeks and late if they had been in place for >6 weeks. Forty-seven explants were early (34 explanted from the mitral position and 13 from the tricuspid position) and 120 were late (40 explanted from the mitral position and 80 from the tricuspid position). After explantation, the bioprostheses were examined grossly, photographed and radiographed. Each cusp was then detached from the stent and divided into 2 halves. One half was submitted for quantitative analysis of calcium using atomic absorption spectrophotometry; the other was subdivided into 3 portions that were used for histologic, transmission electron microscopic and scanning electron microscopic studies.[5]

Results

Incidence of hyaline cartilage in early and late explanted bioprostheses: Hyaline cartilage was not observed in any of the 47 early explants. Hyaline cartilage was found in 16 cusps from 12 of the 120 late explants (10%) (Tables I and II). Seven affected valves were porcine aortic valvular bioprostheses, including 3 standard (not treated with an anticalcification process) Hancock valves, 3 anticalcification-treated (T6 process) Hancock valves, and 1 anticalcification-treated Xenotech valve. The other 5 were pericardial valves, including 1 standard Hancock valve, 2 T6 process Hancock valves, 1 anticalcification-treated Ionescu-Shiley valve and 1 standard Ionescu-Shiley valve. Only 1 of these bioprostheses (a standard Ionescu-Shiley pericardial valve) was explanted from the mitral position; the other 11 were explanted from the tricuspid position (Tables I and II). In late explants, the incidence of hyaline cartilage was 3% in mitral bioprostheses and 14% in tricuspid bioprostheses. These 2 incidences are significantly ($p < 0.01$) different (chi-square method).

Roentgenographic studies: Calcific deposits were detected radiographically in 9 of the 12 valves in which cartilage was found (Table II). The other 3, which were T6-treated Hancock valves, had no radiographic evidence of calcific deposits; however, on histologic examination these 3 valves were found to have very small calcific deposits.

Quantitative calcium analyses: The amounts of calcium present in the cusps of the explanted bioprostheses are shown in Table II. These amounts varied from 1.5 ± 1.4 to 110 ± 35 mg of calcium per gram of tissue dry weight; they did not show a significant correlation with the presence of cartilage, although most of the values were greatly in excess of those in unimplanted valves (<1 mg/g).[4]

Histologic observations: Cartilage was identified in 8 cusps from 7 porcine bioprostheses and 7 cusps from 5 pericardial bioprostheses (Table II). In each of the porcine bioprostheses, cartilage was present in the muscle shelf (Fig. 1A to C); in another cusp of 1 of these valves, cartilage was also found in the fibrous sheath at the base of the cusp.

In 7 cusps from 5 pericardial bioprostheses (Fig. 1D and E), cartilage was located in the fibrous sheath (in the basal third of the cusp in 4, the middle third in 2, and the distal third in 1). Thus, cartilage was not present in pericardial valves unless fibrous sheathing had developed over the affected cusps. In no pericardial valve was the cartilage present within the thickness of the original cuspal tissue. No correlation was observed between the extent of the calcific deposits and the presence of hyaline cartilage.

The nodules of cartilage were composed of chondrocytes embedded in an amorphous matrix that stained metachromatically with toluidine blue and appeared blue in preparations stained with hematoxylin-eosin (Fig. 1E and 2A). Cells that appeared intermediate between fibroblasts and chondrocytes were frequently observed at the periphery of foci of cartilage (Fig. 1E). In 6 cusps (3 from porcine bioprostheses and 3 from pericardial bioprostheses), the foci of cartilage formation were small and consisted of a few chondrocytes embedded in small areas of matrix. In the other 9 cusps (5 from porcine bioprostheses and 4 from pericardial bioprostheses), the cartilaginous foci were more extensive and in a more advanced stage of development. In 1 valve, the chondrocytes were surrounded by calcific deposits and the metachromatic matrix had disappeared almost completely. All foci of cartilage had areas in which the von Kossa reaction for calcium was positive (Fig. 2B). If the formation of cartilage was early, the von Kossa reaction was limited to a few discrete particles; in areas in which cartilage was more extensive and organized, the reaction was more diffuse except for the presence of von Kossa-negative cellular lacunae. In some cusps, areas of metachromatic staining, similar to

that in cartilage matrix, were recognized without any association with chondrocytes. Such areas were not considered to represent cartilage.

An area of bone and bone marrow formation (Fig. 2C and D) was observed in 1 other valve, a standard Ionescu-Shiley pericardial bioprosthesis. Although this valve did not contain cartilage, it is presumed that its bone tissue was formed by a process of calcification of cartilage.

Discussion

Hyaline cartilage is normally found in the heart of numerous species of animals,[6,7] and is usually located in the fibrous ring of the aortic valve. However, cartilage is not normally present in cardiac valves or pericardium, and it has not been described in the aortic valve of the pig or in bovine parietal pericardium, tissues used in the fabrication of the various types of commercially available bioprostheses described in the present study. Hyaline cartilage formation has been induced by ischemia in myocardial tissue,[8] by carrageenan infiltration into aortic wall,[9] by injection of formalin into conductive tissue of the atrial septum to produce heart block,[10] by implantation of devitalized skeletal and cardiac muscle into various sites[11] and by intracardiac implantation of intravenous pacemaker leads[10] and automatic defibrillator leads.[12–14] In addition, mechanical forces have been reported to induce cartilaginous transformation of fibrous connective tissue.[15]

In certain pathologic conditions, hyaline cartilage can be present in hearts and cardiac valves. Small areas of hyaline cartilage were found in the central fibrous body of the heart in 2 children who had sudden cardiac deaths.[16] Cartilaginous tissue also has been described in Mönckeberg's calcific aortic stenosis, although the characteristic pattern of alteration of the aortic valve in this disease is calcification.[17] Cartilaginous transformation of the aortic valve also was reported in a man who underwent aortic valvular replacement for aortic regurgitation of uncertain cause.[18] Foci of cartilage also have been observed in the spongiosa of the atrioventricular valves of dogs with endocardiosis,[19] and cartilage-like cells have been described in the fibrous subaortic ring of dogs with discrete subaortic stenosis.[20] In the present study, we found hyaline cartilage in 10% of 120 bioprostheses explanted from sheep ≥6 weeks after implantation. We are not aware of previous reports of cartilage in bioprosthetic cardiac valves implanted in either humans or experimental animals. In our study,

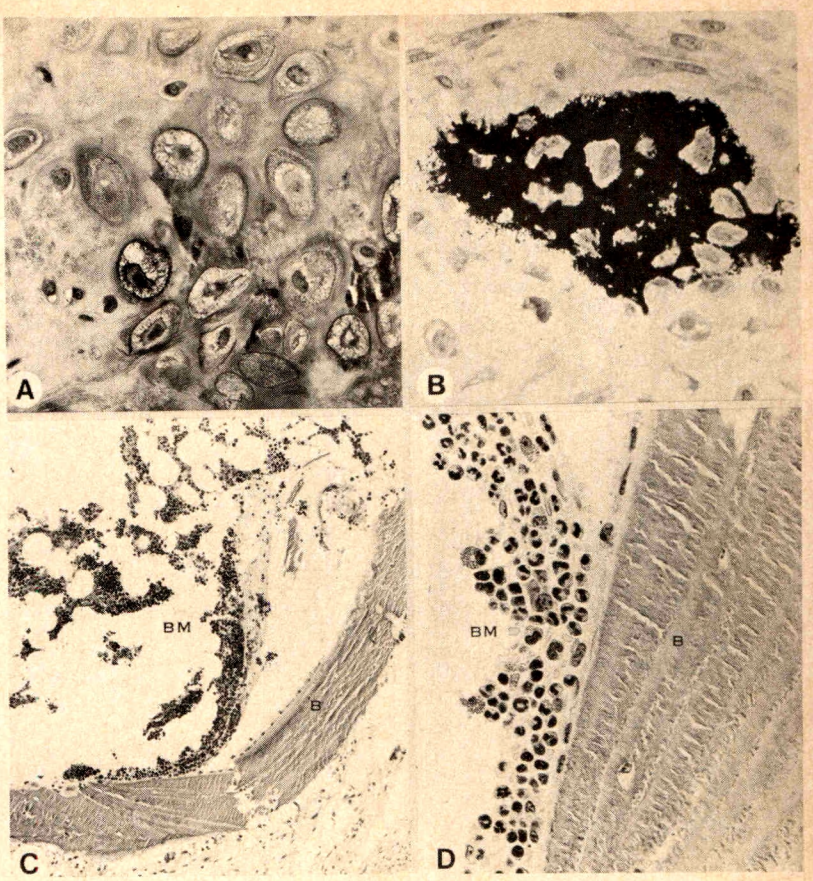

FIGURE 2. A, typical morphologic characteristics of cartilage in bovine pericardial bioprosthesis with chondrocytes lying in lacunae. Note focal calcification (**lower right**). the finding of cartilage could not be correlated with the extent to which calcification was present. However, cartilage was encountered more frequently in bioprostheses implanted in the tricuspid position than in those implanted in the mitral position. The reason for this difference is not known. The consistent finding of a fibrous sheath associated with cartilaginous foci and with transitional cells resembling chondrocytes in cardiac bioprosthetic valves indicates that growing and differentiating connective tissue of host origin plays a role in the cartilage formation. This observation, and the absence of cartilage in valves implanted for <6 weeks, shows that the formation of cartilage was a postimplantation event.

In their description of the mechanically induced differentiation of cartilage from fibrous connective tissue, Scapinelli and Little[15] reported that compression and rotation can cause metaplasia of typical elongated fibrous tissue cells, such as those usually found in fibrous sheaths of bioprostheses,[21] into typical rounded cartilage cells. Whether such forces are related to the formation of the cartilage observed in the present study is not known. We found that cartilage in pericardial bioprostheses usually was associated with the fibrous sheath, and that in porcine bioprostheses was associated with the muscle shelf. The formation of cartilage in the fibrous sheaths of pericardial valves would appear to be similar to that reported in the fibrous sheaths of pacing electrodes[10] and automatic defibrillator leads.[12–14] It has been postulated that devitalized cardiac or skeletal muscle contains a substance that can induce the cartilaginous transformation of primitive mesenchyme.[7,9] This seems to be the case with respect to the cartilage induced in the atrial septum by injection of formalin.[10] Thus, the devitalized cardiac muscle cells in the muscle shelf may be capable, perhaps in conjunction with mechanical forces, of inducing the formation of hyaline cartilage in porcine bioprostheses.

Hyaline cartilage is a specialized type of connective tissue composed of chondrocytes embedded in a matrix rich in proteoglycans. The microscopic appearance of hyaline cartilage in the valves in the present study differs clearly from that of fibrocartilage or elastic cartilage.[22] Chondrocytes can produce matrix vesicles, involved in the process of mineralization (endochondral calcification), which hyaline cartilage can undergo normally.[23] Our observations indicate that cartilage in bioprosthetic valves eventually calcifies, and is 1 of the several causes of mineralization of cuspal connective tissue. Only very limited morphologic observations have been reported in bioprostheses implanted in humans in the tricuspid position, the site from which most (11 of 12) of the cartilage-containing bioprostheses studied by us were explanted. Thus, it remains to be determined whether cartilage formation also occurs in bioprostheses implanted in humans.

Syndromes of Lown-Ganong-Levine and Enhanced Atrioventricular Nodal Conduction

ISAAC WIENER, MD

Intensive investigation has led to major advances in evaluation and therapy of patients with Wolff-Parkinson-White syndrome.[1] The related syndromes of Lown-Ganong-Levine (LGL) and enhanced atrioventricular nodal conduction (EAVNC) have also been studied, but are less well understood. Moreover, LGL, a clinical and electrocardiographic syndrome, and EAVNC, an electrophysiologic syndrome, are often confused. This report examines the current understanding of these subjects.

Definitions: A short PR interval is defined, in the adult population, as a PR interval ≤0.12 second. LGL refers to the association of a short PR interval, a narrow QRS, and tachycardias, most frequently paroxysmal supraventricular tachycardia or atrial fibrillation/flutter.[2] EAVNC refers to functional criteria of atrioventricular (AV) conduction: AH interval in normal sinus rhythm ≤60 ms; 1:1 conduction through the AV node at rates up to 200 beats/min; maximal prolongation of the AH interval ≤100 ms at the fastest rate associated with 1:1 conduction.[3] Patients with LGL frequently do not have EAVNC and many patients with EAVNC do not have LGL.

Anatomic correlations: There is a paucity of data correlating structure and function in LGL and EAVNC.[4] Fibers that skirt the upper portion of the AV node and insert in the lower portion of the node have been described in normal hearts.[5] Whether these fibers assume functional significance as a partial AV node bypass in some patients is unknown. Fibers that run from atrium to His bundle, bypassing the entire AV node, were seen by Brechenmacher[6] in only 2 of 650 autopsied hearts. In 1 patient, a history of atrial fibrillation with a very rapid ventricular response suggested that this pathway had functional significance. Other hypothesized bases for EAVNC are rapidly conducting intranodal fibers, an anatomically normal but small AV node, or an anatomically normal node that exhibits enhanced function.[1]

Clinical Electrophysiology

Patients with short PR intervals: A PR interval ≤0.12 second is found in 2 to 4% of the adult population and represents the lower spectrum of a continuous unimodal distribution, not a distinct group. The short PR interval, in the absence of ventricular preexcitation, represents an AH interval that is either short or at the lower limits of normal. With atrial pacing, some patients have normal AH prolongation with development of AV Wenckebach block at the usual rates. Other patients have AV nodal delay, but in a "blunted" pattern, that is, quantitatively less delay than normal. A very small group of patients has a markedly abnormal "flat" response, with no AH increase as atrial rate is increased, and may have total bypass of the delay producing segment of the AV node.[7–9]

Although in available studies up to 60% of patients with a short PR interval have some abnormality of AV conduction, these are all selected series and the true incidence is probably much lower. Moreover, there are no data attributing any clinical significance to a short PR interval in patients without arrhythmias.

Patients with LGL: short PR interval, narrow QRS, and paroxysmal arrhythmias: Lown et al[2] described paroxysmal supraventricular tachycardia or atrial fibrillation/flutter in 17% of patients with short PR interval and narrow QRS. Ventricular tachycardia has also been described.

The incidence of EAVNC in patients with LGL has not been clearly defined. Benditt et al[10] found EAVNC in 7 of 12 patients with LGL. Given the selected nature of their study population, the true incidence is probably much lower.

Paroxysmal supraventricular tachycardia: Paroxysmal supraventricular tachycardia is the most common arrhythmia in patients with LGL. In some cases this arrhythmia represents reentry using the AV node in the anterograde direction and a concealed bypass tract in the retrograde direction. However, most often, the mechanism is reentry using a slow AV nodal pathway anterograde and a fast AV nodal pathway retrograde.[11,12]

AV nodal reentry is also the most common mechanism of paroxysmal supraventricular tachycardia in patients without LGL. Bauernfeind et al[13] found that in patients with AV nodal reentry, there was no difference in tachycardia rate between those with short and those with normal PR intervals. Although the PR interval reflects anterograde conduction over the fast AV nodal pathway, the rate during tachycardia is largely determined by anterograde conduction time over the slow AV nodal pathway. The same workers subsequently demonstrated that among patients with dual AV nodal pathways, those with a short PR interval were

more likely to have sustained reentrant tachycardias.[14] A short PR interval implies good conduction over the fast pathway from atrium to ventricle and is associated with good conduction over the fast pathway from ventricle to atrium, an important prerequisite for sustained AV nodal reentry. Hence, LGL indicates an increased incidence of sustained AV nodal reentrant tachycardias in patients with short PR intervals.

Atrial fibrillation/flutter: The original report of Lown, Ganong and Levine[2] included 6 patients with paroxysmal atrial fibrillation and 4 with paroxysmal atrial flutter. Two of the patients with atrial fibrillation had sudden cardiac death. Atrial fibrillation and atrial flutter have particular significance in patients with LGL in the presence of EAVNC, in which rates as high as 300 beats/min have been reported.[15]

Ventricular tachycardia/ventricular fibrillation: Ventricular tachycardia has been described in patients with LGL, with and without EAVNC.[11] In patients with EAVNC, conduction of early atrial premature beats may initiate ventricular tachycardia or a very rapid ventricular response to atrial fibrillation may degenerate to ventricular fibrillation.[16,17]

EAVNC: The differentiation between EAVNC and normal AV nodal conduction is, by necessity, arbitrary. Because of the marked sensitivity of the AV node to autonomic tone, rapid conduction of the AV node is frequently seen in situations in which there is increased sympathetic tone, for example, exercise, hypotension or with the administration of sympathomimetic or anticholinergic drugs. Moreover, AV nodal conduction is age-dependent; infants and children often have 1:1 AV conduction at rates that would be abnormally fast for an adult. EAVNC may be present only with pacing from some atrial sites and not others, perhaps reflecting different AV nodal inputs.[18] Recently, EAVNC has been applied to patients who met the single criteria of 1:1 conduction at rates above 200 beats/min.[19] It should be stressed that any definition of EAVNC represents the upper spectrum of a continuous unimodal distribution of normal AV nodal function, rather than a distinct subgroup.[20]

Often there is no electrocardiographic clue to the presence of EAVNC. Benditt et al[10] found a 25% incidence of EAVNC in patients with supraventricular tachycardia and normal PR intervals. Holmes et al[21] reported 42 patients with EAVNC, defined by the single criterion of a 1:1 response at rates above 200 beats/min, and found that only 3 had short PR intervals.

EAVNC has been associated with other bypass tracts, both manifest and concealed.[3,21] In patients with accessory pathways who have paroxysmal supraventricular tachycardia, the AV node forms the anterograde limb of the reentrant circuit and the Kent bundle forms the retrograde limb. The presence of EAVNC allows rapid rates and may make management difficult.

Among patients with EAVNC, it is important to differentiate between those with blunted AH prolongation at rapid rates and those with no AH prolongation. In patients with a blunted response, concealed conduction is seen in the AV node and the ventricular response during atrial fibrillation is only moderately fast. The few patients with a flat response may have total AV nodal bypass and may have very rapid life-threatening ventricular responses to atrial fibrillation.

Pharmacology

LGL without EAVNC: Although limited information is available, these patients appear to respond to drugs like other patients with AV nodal reentry.

EAVNC: Benditt et al[22] 6 patients with EAVNC with atropine and propranolol in doses designed to induce autonomic blockade. The atrial rate at which AV Wenckebach block developed showed a marked decrease, but was still faster than in control subjects. The authors conclude that autonomic changes alone do not explain EAVNC. Nonetheless, the AV node demonstrated a definite response to autonomic blockade. Further studies are necessary.

There is a paucity of systematic information on the response of patients with EAVNC to drugs. Ideally, such information would categorize patients as to whether the AH interval showed a blunted or flat response to atrial pacing. Josephson and Kastor[12] administered propranolol to 1 patient with well-documented EAVNC and blunted response to atrial pacing. Propranolol lengthened the AH interval and caused AV Wenckebach block to appear. Benditt et al[10] studied a single patient with EAVNC with a flat AH response and found that propranolol, digoxin and quinidine had no effect on AV conduction. Kennelly and Lane[23] reported the effects of 0.75 mg of strophanthin in 3 patients with 1:1 conduction at atrial rates of 200 beats/min and blunted response of AH to increased heart rate. In 1 patient, strophanthin decreased the maximal rate at which 1:1 conduction occurred, but in the other 2 there was no effect. Moleiro et al[15] described 2 patients with EAVNC and a blunted AH response. In 1 patient, verapamil caused a marked decrease of ventricular response in atrial fibrillation. In the second patient, who had an associated short HV interval, verapamil and edrophonium had no effect on ventricular response to atrial flutter. Holmes et al[19] reported pharmacologic control in only 10 of 26 patients with EAVNC and a variety of tachyarrhythmias. Most often a Type I antiarrhythmic was used singly or in combination with digoxin or propranolol. Whether the drugs affected the *EAVNC or* had other antiarrhythmic effects is not specified. In patients with Wolff-Parkinson-White syndrome, digoxin and verapamil may increase ventricular response during atrial fibrillation. This response has not been reported in patients with EAVNC.

Hence, there are few systematic data on drug response in EAVNC. AV nodal blocking agents have a role, but are not uniformly effective. In the patient who has rapid tachycardias with debilitating symptoms, electrophysiologic testing of the effects of drugs on AV conduction should be considered.

Patients with refractory arrhythmias: For patients with EAVNC and refractory tachycardias that incorporate an accessory pathway, surgical ablation of the accessory pathway may prevent recurrent supraventricular tachycardia.[21] For patients with EAVNC with intractable rapid atrial fibrillation/flutter, direct

ablation of the His bundle with insertion of a permanent pacemaker is available as a therapy of last resort. His bundle interruption has been achieved intraoperatively using mapping localization and cryosurgical ablation[24] and, more recently, by electrical charges administered through a catheter.[25] These techniques are rarely necessary.

Conclusions: The available data allow the following conclusions. (1) A short PR interval alone is part of the normal distribution and requires no special evaluation. (2) LGL describes an association between short PR interval, narrow QRS, and tachycardias. Although patients with LGL may have a variety of arrhythmias, a short PR interval is associated with excellent retrograde fast pathway conduction in patients with dual AV pathways and, hence, greater propensity to AV nodal reentrant tachycardia. (3) EAVNC may be present in patients with normal or short PR intervals and is defined by arbitrary electrophysiologic criteria including the ability for 1:1 AV conduction at rates of 200 beats/min. EAVNC represents part of the spectrum of AV conduction, not a distinct subgroup, and does not have a clear-cut anatomic substrate. (4) EAVNC assumes clinical significance by allowing very rapid rates during supraventricular arrhythmias. (5) The response of EAVNC to medication is not well-characterized. Although AV nodal blocking agents are frequently effective, their efficacy in the individual patient cannot be predicted. (6) For the rare refractory patient, surgical and catheter ablative techniques are available.

Torsades de Pointes Versus Polymorphous Ventricular Tachycardia

DAN TZIVONI, MD, ANDRE KEREN, MD, and SHLOMO STERN, MD

Torsade de pointes has recently gained much attention; many studies of the cause and management of this interesting and intriguing tachyarrhythmia have been published.[1–4] However, because of an unclear definition of this entity, various investigators included under the term torsades de pointes (TdP) different types of ventricular tachycardia (VT). This editorial attempts to clarify the confusion and to suggest a definition based on the unique electrophysiologic features of this arrhythmia, which requires an unorthodox therapy.

TdP was described by Dessertenne in 1966[5] as a peculiar VT with a twisting QRS axis and polymorphous appearance. The presence of QT prolongation in this form of VT was already mentioned in Dessertenne's original report, but did not receive the appropriate emphasis in this or in many subsequent studies.

From the Heiden Department of Cardiology, Bikur Cholim Hospital, and the Hebrew University–Hadassah Medical School, Jerusalem, Israel.
Manuscript received November 8, 1982; revised manuscript received June 2, 1983, accepted June 3, 1983.
Address for reprints: Dan Tzivoni, MD, The Heiden Department of Cardiology, Bikur Cholim Hospital, PO Box 492, Jerusalem, Israel.

The basic underlying electrophysiologic disorder of TdP is a marked and uneven delay in myocardial repolarization, induced mainly by QT prolonging agents such as quinidine,[4] disopyramide,[6] procainamide,[7] amiodarone[8] and phenothiazines;[9] however, it may occur also with hypokalemia[10] or hypomagnesemia,[11] or even spontaneously.[12] The mechanism leading to TdP is unclear; it could be a result of either an automatic or a reentrant phenomenon.

If the definition of TdP is not strict enough and is based solely on the polymorphicity of the VT, disregarding the QT prolongation, other conditions without delayed repolarization that require completely different therapeutic approaches will also be included. Recently, Horowitz et al[3] studied 21 patients with polymorphous VT, of whom 14 had a normal QT interval; they considered the VT to be TdP. Nine of these patients were successfully treated by QT-prolonging drugs (quinidine or procainamide). Other investigators reported on the efficacy of these drugs in polymorphous VT with normal QT.[1,13] Similarly, during acute ischemia in dogs, polymorphous VT was successfully suppressed with Type I antiarrhythmic drugs when associated with normal QT intervals.[14]

Prolongation of the QT interval is the most important electrocardiographic feature differentiating TdP from polymorphous VT; this distinction has major clinical significance because it is the clue to the correct therapeutic approach. Although polymorphous VT with a normal QT can be treated with QT-prolonging drugs such as quinidine, procainamide, disopyramide and amiodarone, this type of therapy may be disastrous in TdP.[4] The successful therapy of TdP should stem logically from the underlying electrophysiologic disorder, and should therefore be aimed at shortening and possibly unifying the repolarization process. This goal can be achieved by accelerating the heart rate, either by isoproterenol or atropine or by cardiac pacing.[1,4,15,16] The simplest way to accomplish this is by isoproterenol infusion (2 to 8 μg/min), which is usually effective within a few minutes. If this drug is ineffective or is contraindicated, as in patients with acute myocardial infarction, severe angina pectoris or excessive hypertension, cardiac pacing is indicated. Because the arrhythmia is frequently associated with syncopal attacks and may be life-threatening, rapid institution of therapy is mandatory. Cardiologists and the staff of emergency rooms must be able to deliver appropriate therapy. However, if isoproterenol is given erroneously in polymorphous VT without QT prolongation, it may lead to death from intractable VT.

Serious ventricular arrhythmias arise not infrequently during antiarrhythmic therapy with quinidine, procainamide, disopyramide, and other drugs. These arrhythmias may be associated with a normal, a slightly prolonged or an excessively long QT interval. Patients with a normal QT interval, or possibly even those with slight prolongation, may respond to conventional drugs such as lidocaine or procainamide, even if the VT has a polymorphous appearance. However, when the ventricular arrhythmia is associated with a prolongation of the QT interval of $\geq$0.60 second, "true" TdP should be diagnosed[4] and the conventional therapy must be avoided. This arbitrary criterion of 0.60 second, is, we believe, the best breaking point for the diagnosis of TdP.

To prevent confusion and misdiagnosis, we propose that the diagnosis of TdP be based on the following electrocardiographic findings: (1) a prolonged QT interval ($\geq$0.60 second); (2) initiation by a ventricular premature beat with a long coupling interval; (3) twisting QRS axis of the VT; (4) repeated episodes that last for 5 to 20 beats, with spontaneous termination (unless an episode deteriorates into uniform VT or ventricular fibrillation); and (5) between episodes, multiple ventricular premature beats with ventricular couplets and triplets are commonly present.

We recommend limiting the term torsades de pointes to a VT with polymorphous appearance if this is associated with prolonged QT interval. The presence of a QT $\geq$0.60 second should call for either cessation or reduction in the dose of antiarrhythmic drugs that prolong the QT. A history of palpitation, dizziness or syncope in a patient with QT prolongation should raise the possibility of TdP, and if this entity is diagnosed, rapid institution of isoproterenol or cardiac pacing and avoidance of conventional antiarrhythmic therapy is mandatory.

The AJC in September 1958

CAROLE A. WARNES, MB, BS, MRCP, and WILLIAM C. ROBERTS, MD

Surgical Treatment of Mitral Insufficiency (Donald B. Effler)

The September issue contained the final papers of the symposium on mitral regurgitation (MR). The symposium was dominated by surgical contributions, and demonstrates how attention at the time was focused on finding an ideal reparative operation for MR. The circumferential suture reported by Davila had gained some support, but this article described a different technique. Using a transatrial approach, 6 operations were performed with a pump oxygenator: 4 in patients with ostium primum defect and cleft mitral valve and 2 in patients with acquired MR, probably from ruptured chordae tendineae. The mitral cleft was closed by direct suture and a crescent-shaped prosthesis of pressed Ivalon, or woven Dacron®, was then placed on the atrial aspect of the repaired leaflet. The acquired MR was "repaired" by suturing the leaflets together and again covering the repair by the prosthesis (Fig. 1). Effler wrote, "The purpose of prosthesis is to take up the brunt of thrust from the ventricular contraction when the heart is restarted. It has been our fear that the valve, if repaired by suture alone, might fenestrate upon resumption of ventricular pressures." Elective cardiac arrest, still in its infancy, was used and its importance emphasized. "With the aid of cardiac arrest the heart can be lifted from its bed and rotated or displaced in any manner without the hazard of serious cardiac arrhythmia. The flaccid, arrested heart is indifferent to position or manipulation. This is of extreme importance, as it points to the obvious goal that surgeons will strive for—the replacement of a defective valve by a workable prosthetic valve."

Direct Surgical Relief of Coronary Artery Occlusion (Leonard Gottesman)

With the recognition that coronary disease often was caused by localized obstruction, the concept of operative bypass of the obstruction was considered in the late 1950s. Surgical relief of peripheral arterial obstruction had already been developed, and coronary endarterectomy had been successfully performed in humans. In this article, Gottesman described end-to-side anastomosis of the left internal mammary artery to the left circumflex coronary artery in 5 normothermic dogs under general anesthesia, using a temporary shunt for coronary blood supply (Fig. 2). Three dogs had fatal ventricular fibrillation and 2 survived, 1 of which was killed 4 weeks later and found to have a patent anastomosis. The authors concluded that such bypass techniques were feasible, and could restore blood flow distal to coronary arterial obstructions. Before the technique was applied to humans, however, they recognized that extracorporeal pump oxygenators were necessary, and the technique of coronary angiography (then performed by direct aortic puncture) would require perfection. Ten years later, aortocoronary bypass grafting was successfully performed in humans.[1]

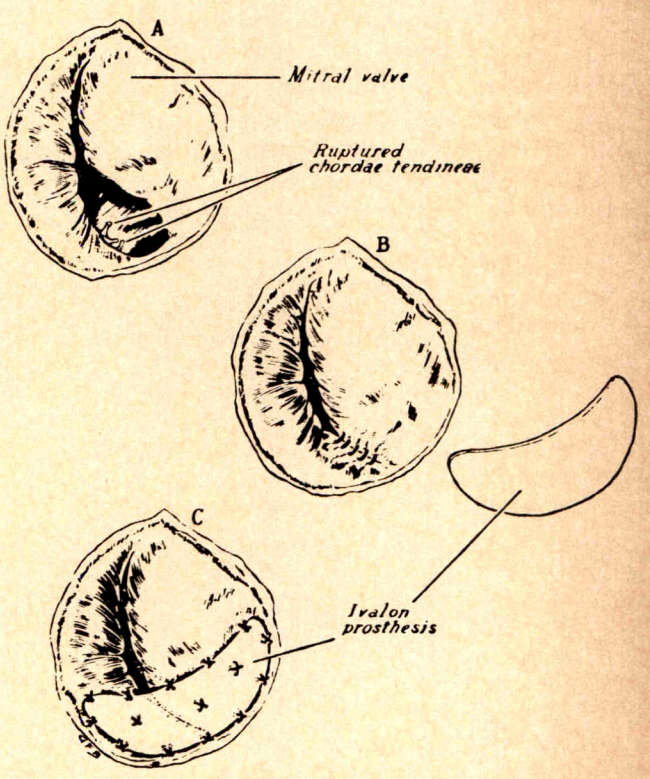

FIGURE 1. Surgical correction of mitral regurgitation performed with the pump oxygenator and elective cardiac arrest. This method is applicable to those valves with localized regurgitation. **A,** the valve with a localized "flail," secondary to ruptured chordae tendineae. **B,** direct suture to obliterate the involved commissure. **C,** reinforcement of the suture line by the crescent prosthesis.

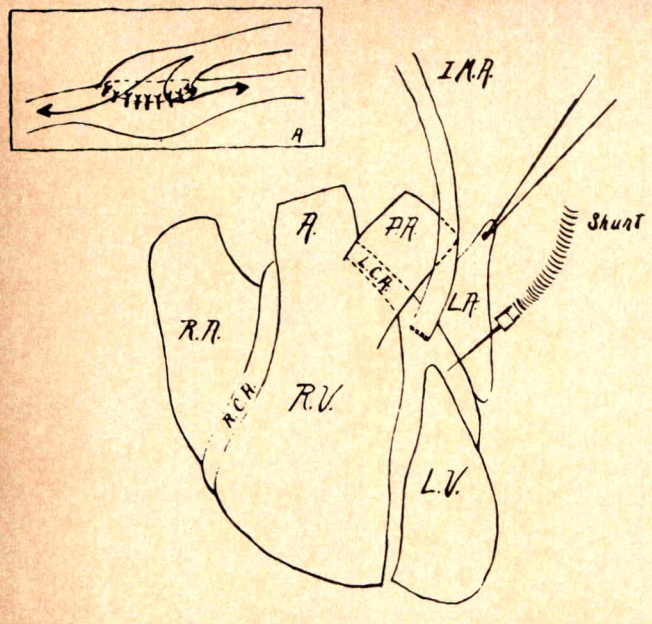

FIGURE 2. End-to-side anastomosis between internal mammary artery (IMA) and left coronary artery (LCA). Inset shows detail of end-to-side anastomosis with bidirectional flow. A = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RCA = right coronary artery; RV = right ventricle.

William Harvey Described by an Eyewitness (John Aubrey) (Saul Jarcho)

This paper consisted of excerpts from John Aubrey's "Life of William Harvey," and gave a lifelike portrayal of this founder of cardiology, complete with his foibles and virtues. The following are some excerpts.

William Harvey, was always very contemplative. . . . I remember I have heard him say he wrote a booke *De Insectis* . . . and had made dissections of Frogges, Toades, and a number of other Animals, and had made curious Observations on them. . . .

I first sawe him at Oxford, 1642, after Edgehill fight, but then was too young to be acquainted with so great a Doctor. I remember he came severall times to Trinity College to George Bathurst, B.D., who had a Hen to hatch Egges in his chamber, which they daly opened to discerne the progres and way of Generation. He was very communicative, and willing to instruct any that were modest and respectfull to him. Ah! My old Friend Dr. Harvey—I knew him right well. He made me sitt by him 2 or 3 hours together in his meditating apartment discoursing. Why, had he been stiffe, starcht, and retired, as other formall Doctors are, he had known no more than they. From the meanest person, in some way, or other, the learnedst man may learn something. Pride has been one of the greatest stoppers of the Advancement of Learning.

I have heard him say, after his Booke of the *Circulation of the Blood* came out, that he fell mightily in his Practize, and that' twas beleeved by the vulgar that he was crackbrained; and all the Physitians were against his Opinion, and envyed him; many wrote against him. With much adoe at last, in about 20 or 30 yeares time, it was received in all the Universities in the world; and, as Mr. Hobbes sayes in his book *De Corpore*, *he is the only man perhaps, that ever lived to see his owne Doctrine established in his life-time.*

All his Profession would allow him to be an excellent Anatomist, but I never heard of any that admired his Therapeutique way. I knew several practisers in London that would not have given 3d. for one of his Bills (prescriptions); and that a man could hardly tell by one of his Bills what he did aime at.

He was much and often troubled with the Gowte, and his way of Cure was thus; he would then sitt with his Legges bare, if it were a Frost, on the leads of Cockaine-house, putt them into a payle of water, till he was almost dead with cold, and betake himself to his Stove, and so 'twas gone.

He lies buried in a Vault at Hempsted in Essex, which his brother Eliab Harvey built; he is lapt in lead, and on his brest in great letters

DR. WILLIAM HARVEY

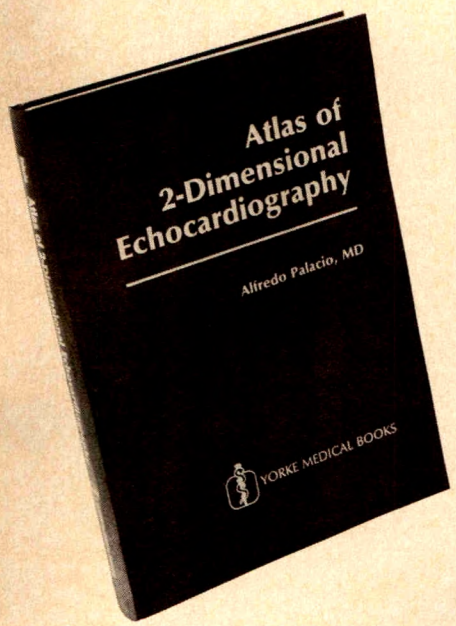
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

Table of Contents

Foreword
Preface
Prologue
Introduction
EQUIPMENT
THE ECHOCARDIOGRAPHIC EXAMINATION
Parasternal position
  Longitudinal plane
  Transverse plane
Apical position
  Hemiaxial plane
  Axial plane
Subxiphoid position
  Transvascular plane
  Transcardiac plane
Suprasternal position
  Longitudinal plane
  Transverse plane
Final recommendations for the beginning technician
Special controls
Compendium of tomographic sections
DISEASES
Mitral stenosis
  Characteristics of the mitral stenosis in 2-dimensional echocardiography
  Longitudinal plane, long axis of the left ventricle
  Transverse plane, short axis
  Direction of future investigations
Mitral regurgitation
Tricuspid valve
Aortic valve and aortic root
Pulmonary valve
Intracardiac masses and tumors
Pericardial effusion
Ischemic heart disease
Congenital heart disease
Cardiomyopathies
Systemic arterial hypertension
MISCELLANEOUS
Valvular prostheses
Performance and volume of the left ventricle
Intracavitary cables and catheters

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

For the salt-sensitive hypertensive

"Salt-sensitive patients with hypertension may have exaggerated sympathetic nervous system response to dietary sodium."[1]

Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

Hypertension

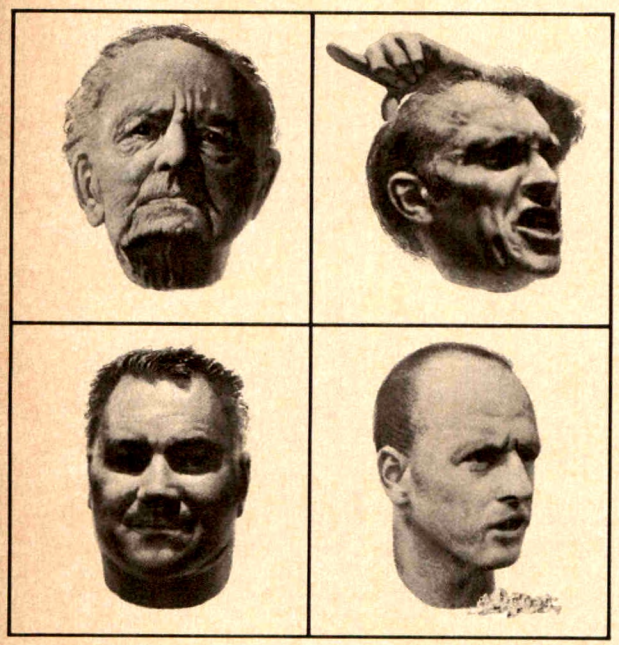
Central control

Please see last page for brief summary, including warnings, **precautions**, and adverse reactions.

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

Catapres®
(clonidine HCl)
Hypertension



Catapres®

(clonidine hydrochloride)

Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

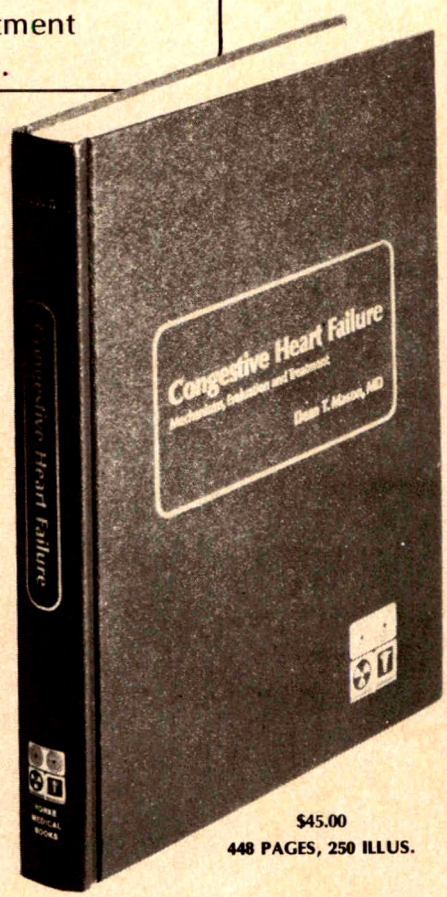
Brings you up-to-date on basic research and clinical progress

Congestive Heart Failure

Mechanisms, Evaluation and Treatment

Dean T. Mason, M.D.



This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

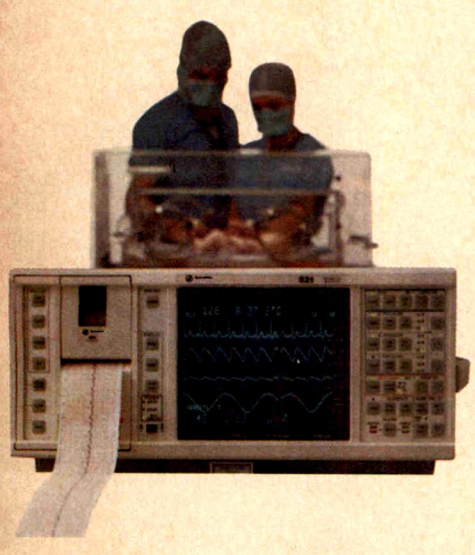
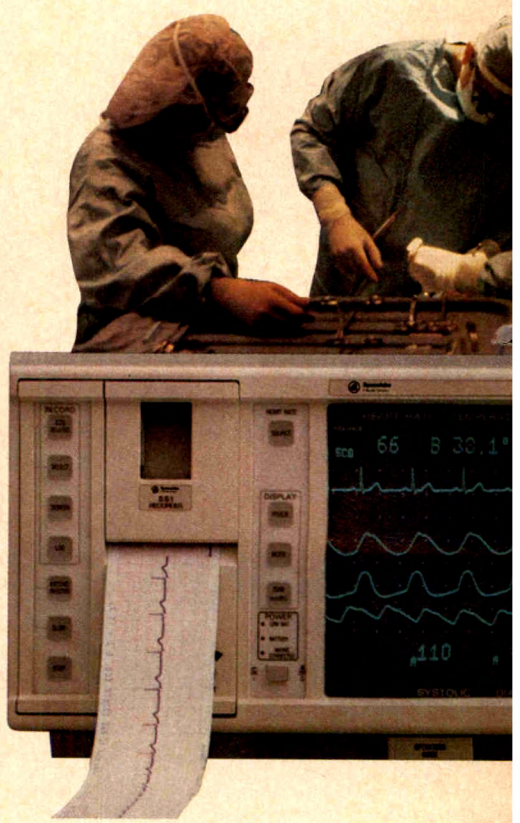
NOW YOU HAVE A CHOICE

Now there is more than one company which can provide you with hospital-wide patient monitoring equipment. The new choice is Spacelabs: for every need, for every level of monitoring required, there is a Spacelabs monitor or system to do the job—accurately, reliably, affordably.

MORE MONITORS...FOR MORE AREAS OF THE HOSPITAL

We have incorporated the well-known portable monitors of Vitatek and the automated noninvasive monitors of Vita-Stat with Spacelabs' patient monitors. The result is a comprehensive line of patient monitoring equipment to meet the broad needs of your hospital...from a simple noninvasive blood pressure monitor to a most sophisticated arrhythmia detection system... from basic, economical stand-alone monitors to a versatile, flexible, multi-bed system, either preconfigured or modular for even greater flexibility...including portable monitors that move with the patient from surgery to the recovery room to the surgical ICU, and telemetry units for ambulatory patients. In fact, every patient who needs monitoring—from neonate to adult, from outpatient to high-risk surgical patient, from acutely ill cardiac patient to one who is in rehabilitation—can benefit from a Spacelabs monitor.





ER REHAB OR RR CCU

Spacelabs
A Squibb Company

MORE EFFICIENT SERVICE NETWORK

The service representatives from our companies are now united into one finely-tuned network—a nationwide service organization dedicated *solely* to patient monitoring equipment, with technical specialists standing by across the country to provide assistance whenever and wherever needed. These specialists understand the complexity of systems and are sensitive to the critical nature of your service needs.

MORE PRODUCT DEVELOPMENT RESOURCES

Uniting the R&D, engineering and quality assurance resources of these companies has produced a large pool of expert design and engineering talent. These individuals are focused sharply on bringing monitoring innovations into clinical practice quickly, efficiently and economically.

As a part of the Squibb Corporation—a multi-billion-dollar healthcare company committed to improving patient care—Spacelabs faces an exciting future, offering your hospital more than just another choice. Whether you need a single monitor or a complete system for one department, or if you are considering standardizing all monitoring equipment throughout your hospital, *call*

800-251-9910

to find out why Spacelabs can be your best choice.

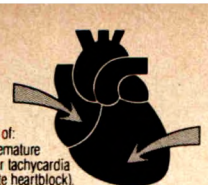
QUINAGLUTE®
(quinidine gluconate)
DURA-TABS®



INDICATIONS AND USAGE:
Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

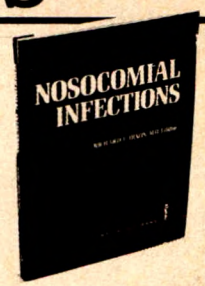
NOSOCOMIAL INFECTIONS

edited by
Richard E. Dixon, M.D.



appx. 344p June 1981,
$35.00 hardbound
ISBN 0-914316-24-9
$22.00 softbound
ISBN 0-914316-29-X

Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

Effect of Interventions in Salvaging Left Ventricular Function in Acute Myocardial Infarction: A Study of Intracoronary Streptokinase*

The University of Alabama School of Medicine designates this continuing medical education activity for 1 credit hour in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marked on the instruction sheet on page A149.

1. Of 52 patients in Germany, acute thrombosis involved:
   a) the right coronary artery in 23 patients
   b) the right coronary artery in 7 patients
   c) the left coronary artery in 7 patients
   d) the left coronary artery in 4 patients

2. Of 108 patients in the University of Washington Hospital, previous myocardial infarction was present in:
   a) 32 of 62 patients with right coronary artery stenosis
   b) 21 of 46 patients with right coronary artery stenosis
   c) 21 of 46 patients with left anterior descending artery stenosis
   d) none of the above

3. In the streptokinase study there were:
   a) 2 groups: streptokinase (STK) plus coronary artery bypass grafting (CABG) and nonrevascularized
   b) 2 groups: STK and nonrevascularized
   c) 3 groups: STK plus CABG, STK, and nonrevascularized
   d) 2 groups: STK plus CABG and STK

4. In patients whose hypokinesia became worse, the decrease in motion was less in:
   a) the STK group than in the STK plus CABG group
   b) the STK plus CABG group than in the STK group
   c) the winter than in the spring
   d) males than in females

5. Hyperkinesia in acute myocardial infarction was similar in patients who did and in those who did not require:
   a) catecholamine support
   b) revascularization
   c) both STK and CABG
   d) none of the above

6. In the present study, the ejection fraction underestimated severity of hypokinesia in acute myocardial infarction and improvement of patients with optimal reperfusion because hyperkinesia:
   a) increased on the wall opposite the myocardial infarction
   b) increased on the wall of the myocardial infarction
   c) decreased on the wall of the myocardial infarction
   d) decreased on the wall opposite the myocardial infarction

7. In this study, none of the patients with rethrombosis had:
   a) ≥ 1 SD/chord improvement in hypokinesia
   b) ≥ 1 SD/chord improvement in hyperkinesia
   c) <2 SD/chord improvement in hyperkinesia
   d) <2 SD/chord improvement in hypokinesia

8. The most sensitive method for measuring hyperkinesia is the:
   a) concentrical method
   b) rectangular method
   c) radial method
   d) centerline method

9. The increase in hyperkinesia in some patients months after myocardial infarction may be due to a chronic compensation associated with:
   a) a low-sodium diet
   b) better global function
   c) maintenance of weight loss
   d) none of the above

10. Chronic hyperkinesia tended to occur more frequently in patients:
    a) with severe hypokinesia in the infarct region
    b) with severe stenosis of the artery opposite the infarct
    c) without severe stenosis of the artery opposite the infarct
    d) all the above

A Simple Method to Interpret Cardiac and Aortic Anatomy From Chest Radiographs

T. JAMES WATERS, MD
RICHARD E. RUBIN, MD
WILLIAM C. ROBERTS, MD

In the training of cardiologists, considerable emphasis is placed on learning proper precordial examination and how to obtain and interpret electrocardiograms, echocardiograms, hemodynamics and contrast and radionuclide angiograms. In contrast, relatively little emphasis is placed on learning how to interpret "routine" radiographs of the chest. This report describes a simple technique to aid in the interpretation of the cardiac and aortic silhouette on the chest roentgenogram.

A 3 × 5 inch (7.6 ± 12.7 mm) card is cut so that it is square (3 × 3 inches) (7.6 × 7.6 mm). On the card, 4 equal-sized circles are drawn, as demonstrated in Figure 1, upper left. The circle closest to the bottom of the card represents the right ventricle (RV), the 1 to the right the right atrium (RA), the 1 toward the top the left atrium (LA) and the 1 to the left the left ventricle (LV). Between the RA and RV, of course, is the tricuspid valve (TV), and between the LA and LV is the mitral valve (MV). The aortic valve (AV) lies in the center surrounded by the circles representing each of the 4 cardiac chambers. The descending thoracic aorta (A) is located to the left of the mitral valve. The esophagus (E) is located between the LA and vertebral bodies.

After these structures are drawn on the 3 × 3 inch card, the ends of a pipe-cleaning wick are placed through the aortic valve and descending aorta and secured by bending the wire on the back of the card. The wick then represents the ascending, transverse and proximal descending thoracic aorta. The bottom of the card represents the anterior chest wall, the right (R) edge the right side of the chest, the top the posterior wall and the left (L) edge the left lateral wall of the chest. The card can now be viewed from the front (Fig. 1, upper left), left lateral position (Fig. 1, upper right), left anterior oblique (LAO) position (Fig. 1, lower left) and right anterior oblique (RAO) position (Fig. 1, lower right) simply by rotating the card.

In the left lateral (LL) position (Fig. 1, upper right) the RV is the most anterior chamber and the LA the most posteriorly located chamber. The LV and RA are midway in between. In the LAO position (Fig. 1, lower left), the RA and RV are to the left and the LA and LV to the right. This is the best view for seeing the ascending and descending thoracic aorta (Ao). In the RAO position (Fig. 1, lower right), the RA and LA form the right lateral border and the RV and LV the left lateral border. The ascending and descending thoracic aorta are superimposed.

This simple 3 × 3 inch index card with the pipe wick can be kept in the wallet or purse until these chamber locations in each of the 4 standard radiographic views are engrained. This simplified approach has made the teaching of radiographic anatomy easy.

Coxsackie Viral Myocarditis Causing Transmural Right and Left Ventricular Infarction Without Coronary Narrowing

JEFFREY E. SAFFITZ, MD, PhD
DAVID J. SCHWARTZ, MD
WILLIAM SOUTHWORTH, MD
SIDNEY MURPHREE, MD
E. RENE RODRIGUEZ, MD
VICTOR J. FERRANS, MD, PhD
WILLIAM C. ROBERTS, MD

Although in adults Coxsackie viral myocarditis is usually an acute, self-limited, benign illness, it can pursue a subacute or chronic course leading to permanent cardiac dysfunction or death.[1] Such was the case in the man described here.

During 1 week, a previously healthly 38-year-old white man had progressively severe dyspnea on minimal exertion without chest pain, fever, recent flu-like syndrome, systemic hypertension, palpitations, orthopnea, paroxysmal dyspnea or heavy alcohol consumption. Examination disclosed complete heart block with a ventricular rate of 40 beats/min, Q waves in the anterior precordial leads, a markedly dilated left ventricle with segmental wall motion abnormalities (Fig. 1), and angiographically normal coronary arteries. Peripheral blood counts and thyroid function study results were normal and serologic test findings for collagen vascular diseases were negative. The erythrocyte sedimentation rate was 21 mm in 1 hour. Antibodies against Coxsackie B-1 were detected in serum at dilutions <1:10 at 1 and 4 weeks after onset of symptoms. After minimal improvement with digoxin, diuretics and permanent pacemaker implantation, symptoms of congestive heart failure (CHF) worsened, and signs of right-sided CHF became severe. The peripheral leukocyte count increased to 19,000/mm^3. Repeat serologic

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, and the Departments of Pathology and Medicine, The Jewish Hospital of St. Louis and Washington University School of Medicine, St. Louis, Missouri. Manuscript received and accepted June 3, 1983.

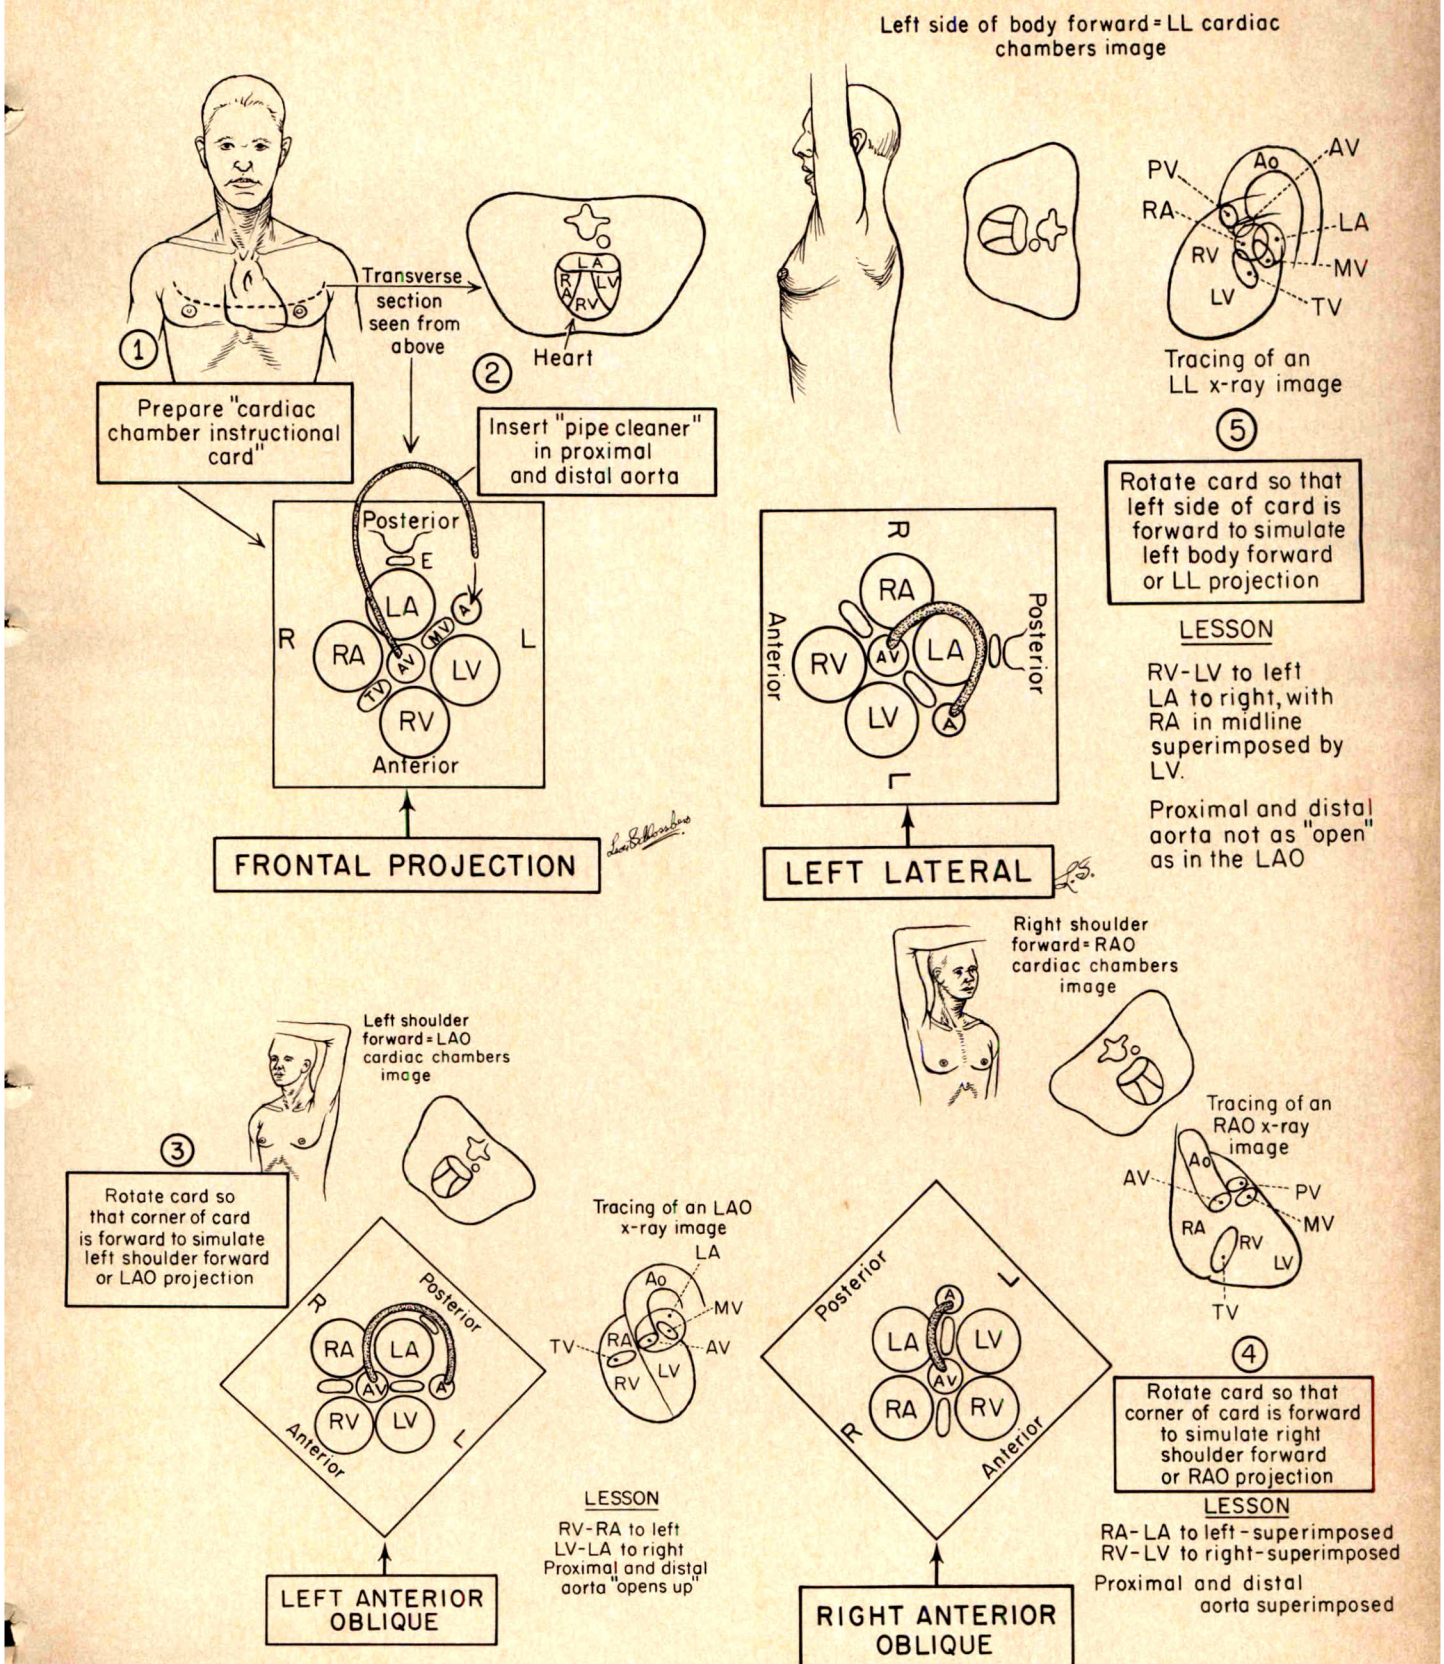

FIGURE 1. Technique described in the text for interpreting the cardiac and aortic silhouette on the chest roentgenogram. PV = pulmonic valve; other abbreviations are as defined in the text.

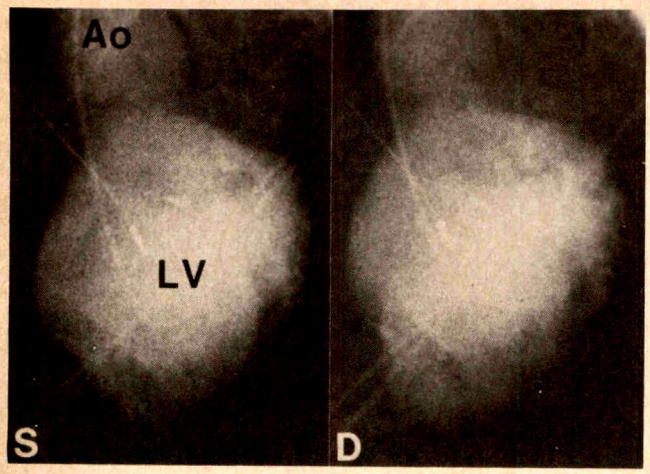

FIGURE 1. Left ventriculogram (cranial left anterior oblique projection) showing end-systolic (S) and end-diastolic (D) ventricular configurations. There are segmental wall motion abnormalities with less severe hypokinesia of the apical and proximal septal segments. Ao = aorta; LV = left ventricle.

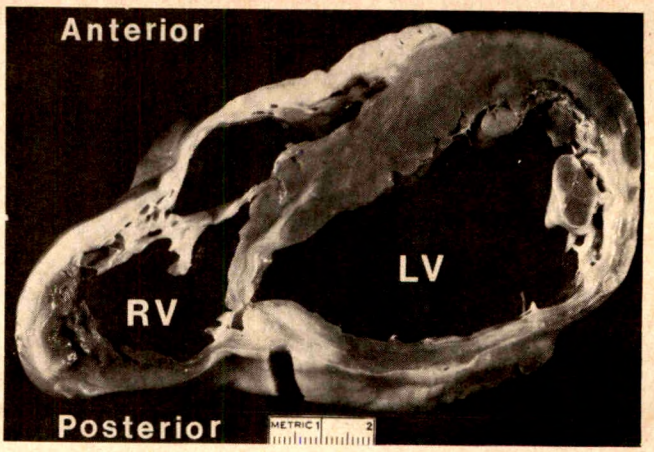

FIGURE 2. Portion of cardiac ventricles cut transversely showing markedly dilated right and left ventricles (RV and LV). Much of the anterolateral wall of the RV and posteroseptal and lateral walls of LV are replaced by scar tissue.

studies 4 months after onset of symptoms disclosed a >12-fold increase in antibodies against Coxsackie B-1 (>1:128) without increases in other viral antibodies. The patient died 4.5 months after the onset of symptoms from severe CHF.

At necropsy (The Jewish Hospital of St. Louis, #A82-83), the heart weighed 470 g. Both ventricular chambers were markedly dilated (Fig. 2). Much of the anterolateral wall of the right ventricle, the posterolateral wall of the left ventricle and the posterior portion of the ventricular septum was replaced by fibrous tissue (Fig. 2). The coronary arteries were insignificantly (<25% cross-sectional area) narrowed. Histologic examination discosed extensive lymphocytic infiltrates, fibrous tissue and necrotic and degenerated myocytes (Fig. 3). Ultrastructural examination of myocardium did not disclose Coxsackie viral particles.

Coxsackie B-1 myocarditis, documented by serologic tests, had an unusually virulent course, causing profound CHF and widespread myocardial destruction in our patient. The noncardiac organs and tissues, including skeletal muscle, were not involved by the inflammatory process. An unusual feature was extensive transmural scarring of the walls of both ventricles, which resulted in segmental wall motion abnormalities. Studies in experimental models have documented CHF as a complication of viral myocarditis[2] and suggest a role of viruses in the pathogenesis of idiopathic dilated cardiomyopathy. Transmural right and left ventricular

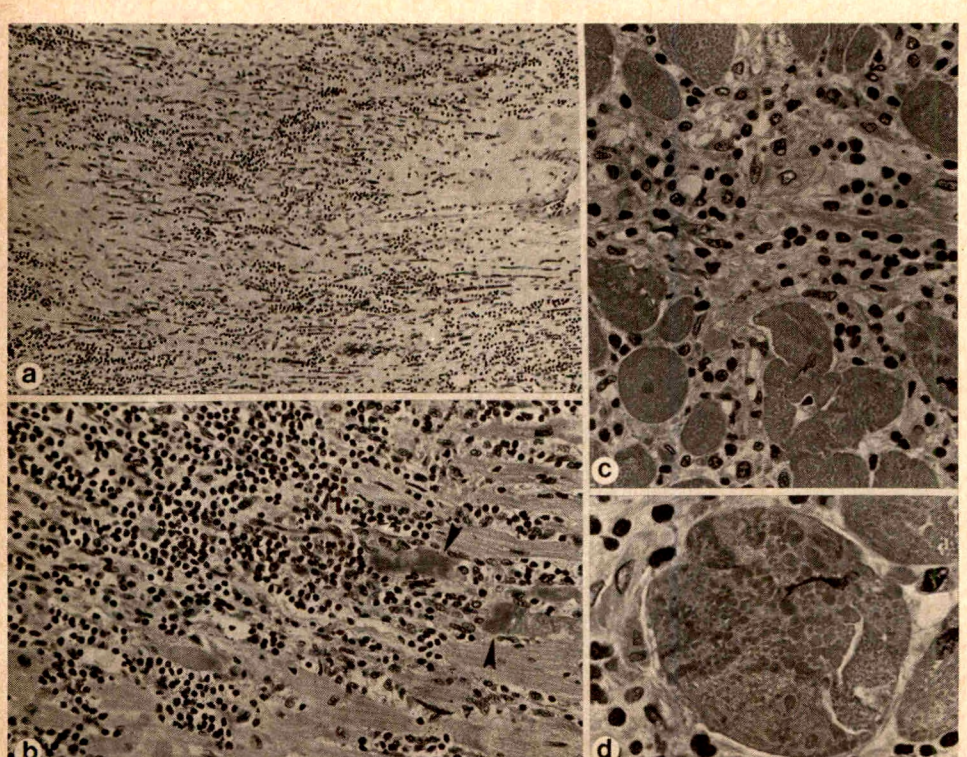

FIGURE 3. Photomicrographs of portions of left ventricle. **a,** area of left ventricular free wall showing extensive lymphocytic infiltrate and replacement of the myocytes by fibrous connective tissue. **b,** higher magnification view of border zone between viable myocardium (right) and scar tissue (left) showing numerous lymphocytes and focally necrotic myocytes (**arrowheads**). **c,** 1-μm-thick sections of left ventricular free wall showing an area of interstitial fibrosis, myocytic hypertrophy, and lymphocytic infiltrates. The myocytes vary in diameter. **d,** Large, hypertrophied, degenerating myocyte showing loss of myofibrils. scarring is rare in patients with idiopathic dilated cardiomyopathy. In 1 reported patient, a 62-year-old woman with symptoms of cardiac dysfunction from dilated cardiomyopathy for 9 years, necropsy disclosed cardiac findings nearly identical to those in the patient described herein, except that inflammatory cells were absent in the scarred myocardium.[3]

Active Infective Endocarditis Complicating Idiopathic Dilated Cardiomyopathy

MARC A. SILVER, MD
WILLIAM C. ROBERTS, MD

The occurrence of infective endocarditis in patients with habitual alcoholism is fairly frequent.[1] A high percentage of patients with idiopathic dilated cardiomyopathy are habitual alcoholics. Yet, the occurrence of infective endocarditis in patients with idiopathic dilated cardiomyopathy is extremely rare. Such was the case, however, in the patient described here.

AW, a 60-year-old man, had been a habitual alcoholic for many years and had the onset of chronic congestive heart failure (CHF) at age 53 years. About 1 year before death, periodic ventricular tachycardia with syncope occurred and he had 2 episodes of ventricular fibrillation with successful resuscitation. The ejection fraction was 19%. His final hospitalization was precipitated by worsening CHF. The blood pressure was 100/80 mm Hg and the temperature 37°C. A grade 3/6 systolic blowing murmur was heard over the cardiac apex. Four of 4 blood cultures grew Staphylococcus aureus *and a chest radiograph showed an infiltrate consistent with acute pneumonia in each lung. Death was attributed to progressive CHF and pneumonia.*

At necropsy, the heart weighed 595 g. The coronary arteries were virtually devoid of atherosclerotic plaques. A thrombus was present in the right atrial appendage. All 4 cardiac chambers were dilated, particularly the ventricles. Several mural endocardial white plaques were present in the left ventricle. A vegetation that measured about 1 cm in maximal diameter and consisted of colonies of Gram-positive organisms, pus and fibrin was present on the atrial aspect of the posterior mitral leaflet (Fig. 1 and 2). The underlying leaflets and chordae tendineae were normal.

Of 165 patients with idiopathic dilated cardiomyopathy studied at necropsy in the Pathology Branch of the National Heart, Lung, and Blood Institute, the patient described in this report is the only 1 with evidence of either active or healed infective endocarditis; we are not aware of any published reports that mention infective endocarditis complicating idiopathic dilated cardiomyopathy. The endocarditis in our patient was probably a consequence of the acute pneumonia, since similar colonies of organisms were present in both the lung and the mitral vegetation.

It has been recognized for decades that active infective endocarditis is a rare occurrence in patients with chronic CHF. Our patient is an exception and illustrates that on rare occasion, a patient with extremely diminished cardiac output can still develop infective endocarditis, even on a previously anatomically normal valve. The endocarditis in our patient was probably secondary to the acute pneumonia. Had the pneumonia not been present, the infective endocarditis likely would not have occurred.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received and accepted June 3, 1983.

Acute Pulmonary Edema Induced by Left Bundle Branch Block

MALEAH GROVER, MD
ROBERT L. ENGLER, MD

The hemodynamic effects of altered electrical activation and the subsequent altered mechanical contraction during left bundle branch block (LBBB) in man and experimental preparations are controversial.[1–5] The apparently different reported hemodynamic effects of LBBB may, in part, be due to different underlying cardiac diseases. At issue is whether abnormal activation sequence can result in depressed ventricular function. Acute pulmonary edema caused by LBBB has not previously been described, but did occur in a patient with dilated cardiomyopathy and normal coronary arteries. This patient is described in this report.

A 54-year-old man first had cardiomegaly at age 19 years, first noticed exertional dyspnea at age 45 and severe dyspnea, orthopnea, and paroxysmal nocturnal dyspnea at age 49. Cardiac catheterization (Table I) demonstrated marked left ventricular (LV) dilation, an ejection fraction of 21%, no mitral regurgitation, and normal coronary arteries. Increased dyspnea despite digoxin, furosemide, procainamide, amrinone, prazosin, and potassium chloride led to hospitalization.

Blood pressure was 92/64 mm Hg, heart rate 74 beats/min, and respirations 26 breaths/min. Jugular venous pressure was abnormally increased, and the a wave was dominant. Bilateral basilar rales were present. LV apical impulse was diffuse with presystolic expansion. S_1 and S_2 were normal. A grade 1/6 holosystolic murmur was heard at the apex. Atrial and ventricular diastolic gallops were present. Neither hepatomegaly nor subcutaneous edema was present.

The chest radiograph demonstrated cardiomegaly and pulmonary venous hypertension. The electrocardiogram (Fig. 1) showed sinus rhythm, left atrial enlargement, ST-T abnormalities, and a nonspecific intraventricular conduction delay (IVCD, QRS width 0.11 second).

The patient had 3 episodes of acute pulmonary edema, all associated with the onset of LBBB (QRS width 0.15 second). A premature atrial contraction initiated LBBB at a faster heart rate (Fig. 2). In 15 minutes, the patient was acutely dyspneic, the holosystolic murmur increased 1 grade in intensity, and a large V wave was seen in the pulmonary artery wedge pressure (Table I). The electrocardiogram reverted to the IVCD and the pulmonary edema resolved. He was taken to the catheterization laboratory, where baseline data were obtained at a heart rate of 80 beats/min (Fig. 3, top). Brief atrial pacing at a rate of 102 beats/min initiated LBBB; when atrial pacing was stopped, LBBB persisted at a rate of 84 beats/min. Repeat hemodynamic measurements were obtained after 3 minutes. Transient sinus slowing produced by carotid sinus massage resulted in reversion to IVCD. Recovery hemodynamic measurements were obtained after 3 minutes. Accompanying the LBBB, the mean pulmonary artery wedge pressure and V wave increased (Fig. 3, middle), as did the pulmonary artery pressure, pulmonary vascular resistance, and arteriovenous oxygen difference (Table I). Cardiac output did not change and the systemic arterial pressure decreased slightly. These values returned toward baseline values after reversion of the electrocardiogram to the IVCD (Table I, Fig. 3, bottom).

* Cardiac output in 1982 was determined by the thermodilution method.
† Heart rate during angiography.
AVO_2 = arteriovenous oxygen difference; HR = heart rate; LBA = left brachial artery; LBBB = left bundle branch block; LV = left ventricle; PA = pulmonary artery; PAW = pulmonary artery wedge; PVR = pulmonary vascular resistance; RA = right atrium; RV = right ventricle.

In this patient, rate-related LBBB (that is, altered LV activation) was shown clearly by a sequential study to result in pulmonary edema. Two possible causes of the pulmonary edema are decreased cardiac performance and increased mitral regurgitation. Impaired LV hemodynamic function was likely produced because the mean filling pressure increased from 20 to 28 mm Hg at a lower LV systolic pressure and with little change in the forward stroke volume, suggesting that this ventricle was operating on a depressed function curve during LBBB. Haft et al[6] studied 24 patients with LBBB (7 with coronary artery disease, 5 with cardiomyopathy, and 7 with valvular disease) and found that only patients with coronary artery disease had abnormal LV contraction. Williams et al[7] studied 12 patients with LBBB without significant coronary disease; using biplane cineangiograms and quantitative analysis, 10 had wall motion abnormalities.

An additional likely cause of the acute increase in mean pulmonary arterial wedge pressure and in the development of a large V wave is the development of

increased mitral regurgitation with the onset of LBBB. Increased mitral regurgitation during LBBB may be caused by either an alteration in the timing of contraction of the papillary muscles or an alteration in the shape of the mitral valve anulus or both. The latter explanation would imply that the regurgitation may have followed LV enlargement due to depressed function. Alteration in the timing of contraction of the papillary muscles and adjacent LV myocardium as occurs in LBBB might further distort the mitral valve anulus to cause increased mitral regurgitation. The results in our patient suggest that abnormal ventricular activation can result in clinically significant LV dysfunction, at least in patients with abnormal LV myocardium.

Diagnosis of Left Ventricular to Right Atrial Shunt Utilizing Contrast Echocardiography

JEFFREY G. SHANES, MD
SIDNEY LEVITSKY, MD
M. SALEEM SEYAL, MD
WILLIAM WELCH, MD
GEORGE KONDOS, MD
NORMAN SILVERMAN, MD
STUART RICH, MD
RAYMOND J. PIETRAS, MD

A left ventricular (LV)-to-right atrial (RA) shunt is an uncommon condition that usually results from a congenital defect.[1] Rarely, such lesions may be acquired after infective endocarditis,[2] valve replacement[3] or trauma.[4] We describe a case in which a LV–RA fistula occurred after aortic valve replacement. The echocardiographic findings were diagnostic.

A 23-year-old man, an intravenous drug abuser, developed severe aortic regurgitation (AR) with stroke from Staphylococcus aureus *endocarditis. Twelve days after the initial onset of symptoms, heart surgery was performed and confirmed the clinical, echocardiographic and angiographic findings of a ring abscess involving the aortic valve noncoronary cusp and severe destruction of the aortic valve cusps and septal leaflet of the triscupid valve. Debridement of the abscess cavity, excision of the septal leaflet of the tricuspid valve, and aortic valve replacement with a 23-mm Ionescu-Shiley prosthetic valve was performed. On the 29th postoperative day, a new diastolic murmur was heard, which was loudest at the upper right sternal border. The hemodynamics were stable and blood cultures were negative; the patient was discharged 2 months after surgery.*

From the Division of Cardiology and the Division of Cardiothoracic Surgery, University of Illinois, Chicago, Illinois. Manuscript received February 22, 1983; revised manuscript accepted April 13, 1983, accepted April 19, 1983.

During the next 10 months the appearance of ascites, peripheral edema and jaundice necessitated readmission. Examination revealed a grade 3/6 systolic murmur, a grade 3/6 diastolic murmur best heard at the lower left sternal border, and findings compatible with moderately severe tricuspid regurgitation. Aortic root angiography revealed mild AR and an aneurysm of the sinus of Valsalva. Left ventriculography demonstrated a ventricular septal defect; however, visualization of the right-sided chamber was inadequate to determine if the shunt entered the right atrium or right ventricle. Blood samples for oxygen saturation were obtained from the pulmonary artery, right atrium and left ventricle and were compatible with a 2:1 left-to-right shunt, but because of severe tricuspid regurgitation the exact level of the shunt could not be determined. However, 2-dimensional saline contrast echocardiography performed later revealed the defect and accurately delineated the chambers involved (Fig. 1). At operation, the echocardiographic finding of the LV-RA fistula was confirmed. The defect was approximately 1.5 cm in diameter and was closed with pledget sutures. The tricuspid valve was replaced with a porcine heterograft prosthesis. Postoperatively, ascites, jaundice, peripheral edema and hepatomegaly resolved completely.

The unique feature of this case was the use of 2-dimensional echocardiography, which allowed us to visualize the defect and accurately predict its anatomic location. Because the size of acquired LV-RA fistula has generally been >0.4 cm, echocardiographic visualization of these fistulas would appear feasible. In our patient, the identification of the defect was best accomplished in the short-axis view at a level just below the aortic valve; the defect also was seen in the apical long-axis view, but with far less clarity.

Thrombocytosis and Fatal Coronary Heart Disease

JEFFREY E. SAFFITZ, MD, PhD*
EDWIN R. PHILLIPS, MD, PhD
PETER N. TEMESY-ARMOS, MD
WILLIAM C. ROBERTS, MD

Although thrombocytosis may cause vascular thrombosis with resultant organ or tissue ischemia, the occurrence of coronary thrombosis and myocardial infarction (MI) in this circumstance is rare. To our knowledge, this association has been reported only once previously, in a 22-year-old man.[1] In this report, we describe another 22-year-old man with fatal congestive heart failure almost a year after a large MI associated with thrombocytosis.

A 22-year-old man developed intermittent hematuria at age 5 years and systemic hypertension and proteinuria at age 7 years. Although the hypertension and proteinuria persisted, extensive evaluation at age 19 years, including renal biopsy, disclosed no specific abnormalities. The platelet count at that time was 231,000/mm^3. At age 21 years, sudden, severe precordial pain appeared and an acute anterior wall MI was documented. The platelet count ranged from 400,000 to 600,000/mm^3. The MI was complicated by ventricular arrhythmias and thromboemboli, which required embolectomy in both legs. A month after onset of the acute MI, congestive heart failure (CHF) prompted catheterization, which disclosed total occlusion of the right and left anterior descending coronary arteries (R and LAD) and an apical left ventricular (LV) aneurysm. The total serum cholesterol level was 174 mg/dl. Sudden pain, cyanosis and coolness of the left index finger occurred 6 months after the acute MI. At that time, he underwent embolectomy of the left brachial and radial arteries and the LV aneurysm in the anterior wall was excised. The aneurysm contained thrombus. CHF persisted and he was hospitalized several times. The platelet counts

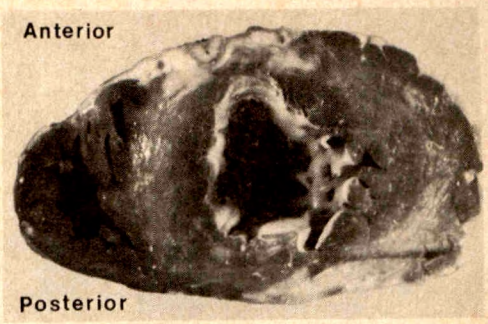

FIGURE 1. A transverse section of the heart at necropsy showing healed infarcts in the anterior and posterior left ventricular walls and fresh mural thrombus overlying dense white endocardial fibrous tissue.

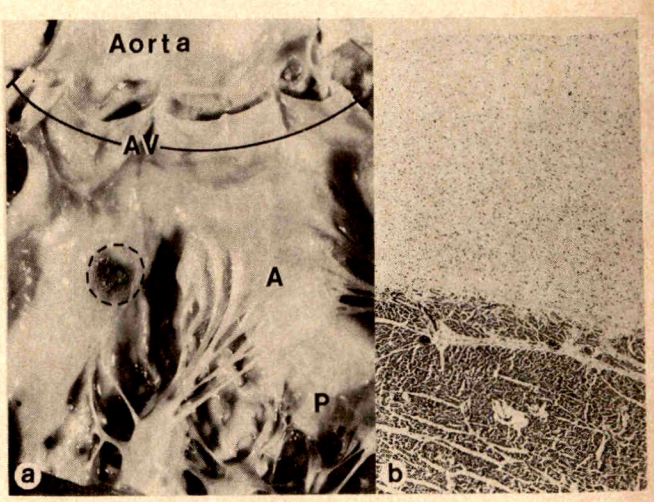

FIGURE 2. a, Opened left ventricle, aortic valve (AV) and aorta showing markedly thickened endocardial fibrous tissue overlying scarred myocardium. Enclosed in the dashed circle is a small thrombus. A and P = anterior and posterior mitral leaflets. **b,** Photomicrograph showing fibrous tissue overlying mural endocardium. The connective tissue is similar to that in the lumen of the occluded epicardial coronary arteries. Hematoxylin-eosin stain; magnification ×54, reduced 44%.

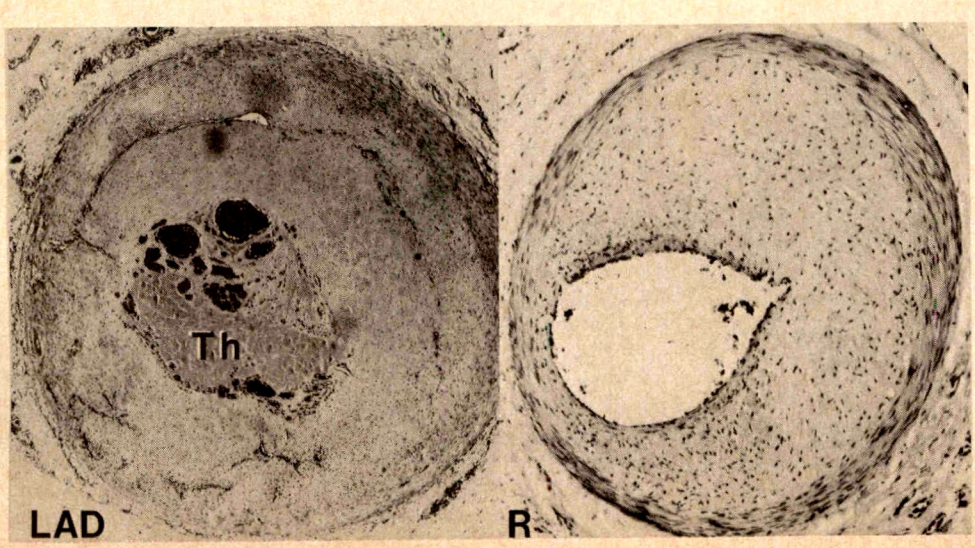

FIGURE 3. Photomicrographs of a cross section of the left anterior descending coronary artery (LAD) and a branch of the right coronary artery (R). The LAD is severely narrowed by fibrocellular tissue. Multiple channels and fresh platelet-fibrin thrombus (Th) are present. The branch of the right coronary artery is narrowed by connective tissue, similar to that shown in Figure 1. Neither vessel contains foam cells, cholesterol clefts, calcific deposits or pultaceous debris. Hematoxylin-eosin stains; magnification ×38 (LAD), ×107 (R); reduced 25%.

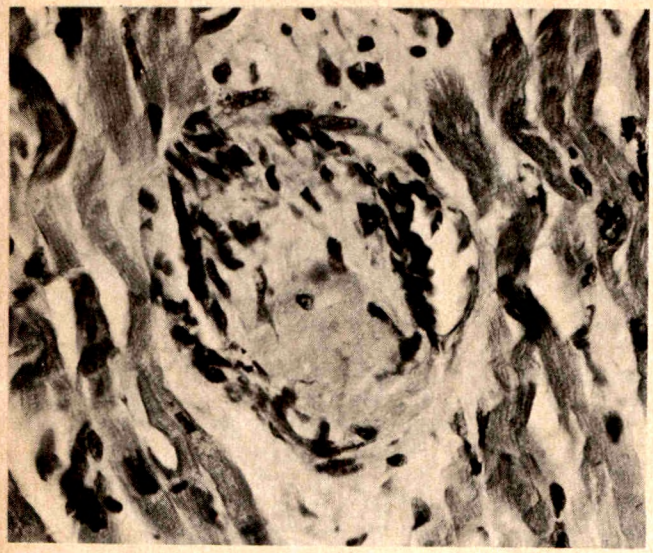

FIGURE 4. Photomicrograph of portion of left ventricular myocardium showing small intramural coronary artery containing platelet-fibrin thromboemboli. Hematoxylin-eosin stain; magnification ×430, reduced 13%.

ranged from 400,000 to 800,000/mm³. The final hospital admission at age 22 years was necessitated by severe CHF and ischemia of the distal left fourth finger. Cardiac output and blood pressure diminished progressively and the patient died 10.5 months after the acute MI.

At necropsy (Medical College of Ohio #A-82-2), the heart weighed 450 g. The apical half of the anterior LV free wall was replaced by dense scar at and adjacent to the LV aneurysectomy incision (Fig. 1). The posterior LV wall was also scarred. The LV apex contained mural thrombus adherent to underlying endocardial fibrous tissue. Fresh and organized mural thrombus also covered the LV outflow tract (Fig. 2). The R and LAD were totally occluded proximally; the length of the LAD occlusion was approximately 2 cm and that of the R 4 cm. The other portions of the LAD and R and the entire left circumflex artery were normal. Branches of the major epicardial coronary contained discrete focal severe narrowings with normal intervening areas. Histologic examination of the narrowed coronary arterial segments showed fibrocellular intimal profileration without foam cells, cholesterol clefts, pultaceous debris or calcific deposits (Fig. 3). In some segments, the lumen contained several small channels, and a platelet-fibrin thrombus was present in the LAD (Fig. 3). The intima of the narrowed coronary arteries was similar histologically to the thickened fibrous tissue on the LV mural endocardium (Fig. 4). Histologic examination of LV myocardium disclosed necrosis adjacent to the healed MI and multiple small intramural coronary vessels with platelet-fibrin thromboemboli (Fig. 4). Both the spleen and lung contained discrete infarcts. The aorta was free of atherosclerotic plaques. The bone marrow, specifically the megakaryocytes, was normal. The kidneys contained focal hyaline sclerosis of glomerular capillary tufts consistent with organized microthrombi, but no other abnormalities to explain the hematuria and proteinuria throughout childhood. (Sections of kidney were examined by John M. Kissane, MD, a recognized renal expert, who agreed with our renal diagnosis.)

Thrombocytosis appears to be the only reasonable cause of the fatal coronary artery disease in the patient described here. The presence of thromboemboli in the intramural coronary arteries, in peripheral, splenic, pulmonary and renal arteries, the young age of the patient, the morphologic features of the luminal material that caused the multiple arterial narrowings (that is, its dissimilarity to atherosclerotic plaques) all strongly support the view that the arterial narrowings in this patient were the result of thrombocytosis.

Left Ventricular Outflow Obstruction Caused by a Starr-Edwards Mitral Prosthesis

PETER C. D. PELIKAN, MD
PAUL H. CHEW, MD
NICHOLAS J. FORTUIN, MD
FRANK C. P. YIN, PhD, MD

The Starr-Edwards caged-ball prosthesis is the most bulky prosthesis and might be expected to have unique complications, especially when used in the mitral position in a small ventricle. This report documents left ventricular (LV) outflow tract obstruction caused by a Starr-Edwards prosthesis in the mitral valve (MV) position.

From the Cardiology Division, Department of Medicine, Johns Hopkins Medical Institutions, Baltimore, Maryland. Manuscript received April 22, 1983; revision received May 13, 1983, accepted May 17, 1983.

N.H. was evaluated in 1972, when she was 61 years old, because of progressive dyspnea on exertion and atrial fibrillation. She had findings typical of mitral stenosis and no systolic precordial murmur. Her weight was 69 kg and her height was 173 cm. Cardiac catheterization confirmed mitral stenosis with a mean MV gradient of 12 mm Hg (cardiac output 3.15 liters/min) and an estimated MV area of 0.6 cm². The ejection fraction was 56% and the LV cavity was small (end-diastolic volume 48 ml). No aortic valve gradient was noted. Mild mitral regurgitation, trivial aortic regurgitation, and moderate pulmonary hypertension (pulmonary artery pressure 44/28 mm Hg) were noted. The patient underwent uncomplicated MV replacement with a Starr-Edwards model 6320 (size 2m) prosthesis.

In 1982, 10 years after MV replacement, catheterization was again performed to evaluate a systolic murmur that had become progressively louder over the past 7 years. A 2-dimensional echocardiogram (Fig. 1) showed normal motion of the poppet throughout the cardiac cycle. The prosthesis was positioned abnormally, with protrusion of the cage and ball into the LV outflow tract. At catheterization, the mean MV gradient was 8 mm Hg and there was no mitral regurgitation. Two slow pullbacks from left ventricle to aorta with an end-hole catheter (No. 8 Fr. right, Judkins USCI) showed

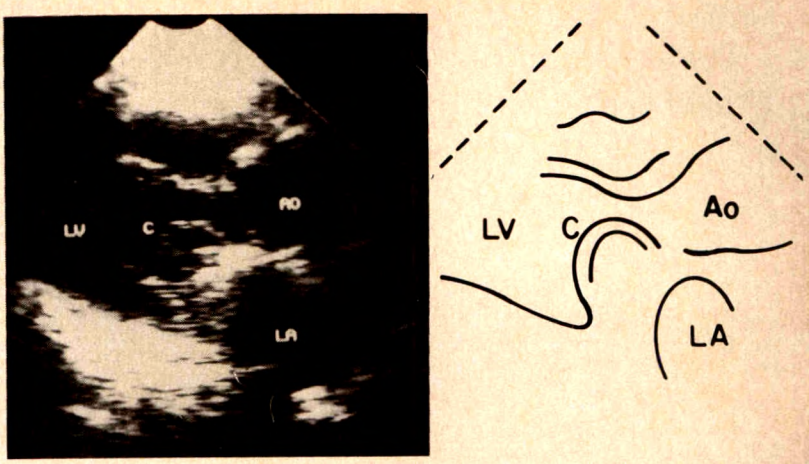

FIGURE 1. Two-dimensional echocardiogram and schematic reproduction in the left parasternal long-axis view. The prosthetic valve cage (C) projects into the outflow tract between the left ventricle (LV) and aorta (AO). The left ventricle and left atrium (LA) are of normal size.

a 50 to 70 mm Hg intraventricular gradient, well localized between the LV body and the subaortic valve outflow tract, corresponding to the position of the prosthetic MV ball and cage. There was no transvalvular aortic gradient (Fig. 2).

Despite previous suggestions that LV outflow obstruction could be caused by a Starr-Edwards MV prosthesis, this is the first report to confirm this phenomenon hemodynamically. The potential for LV outflow tract obstruction by such a prosthesis has been suggested by autopsy study,[1] preoperative echocardiography[2,3] and postoperative outcome.[4] As in our patient, 2-dimensional echocardiography may suggest the diagnosis by showing abnormal projection of the prosthesis into the LV outflow tract rather than into the body of the left ventricle. Continuous-wave Doppler ultrasound[5] may also aid in the diagnosis of such obstruction. At present, the diagnosis is still probably best confirmed by slow pullback with an end-hole catheter or, better yet, with a double sensor micromanometer.

Although LV outflow tract obstruction appears to be a rare complication of MV replacement with a Starr-Edwards mitral prosthesis, the development of a new systolic murmur should alert the cardiologist to differentiate LV outflow tract obstruction from valvular aortic stenosis, or even paravalvular or transvalvular regurgitation. The benign course of this patient over the 7 years after development of a new systolic murmur, with no development of LV hypertrophy, suggests that this may be a well tolerated lesion that does not necessitate surgery.

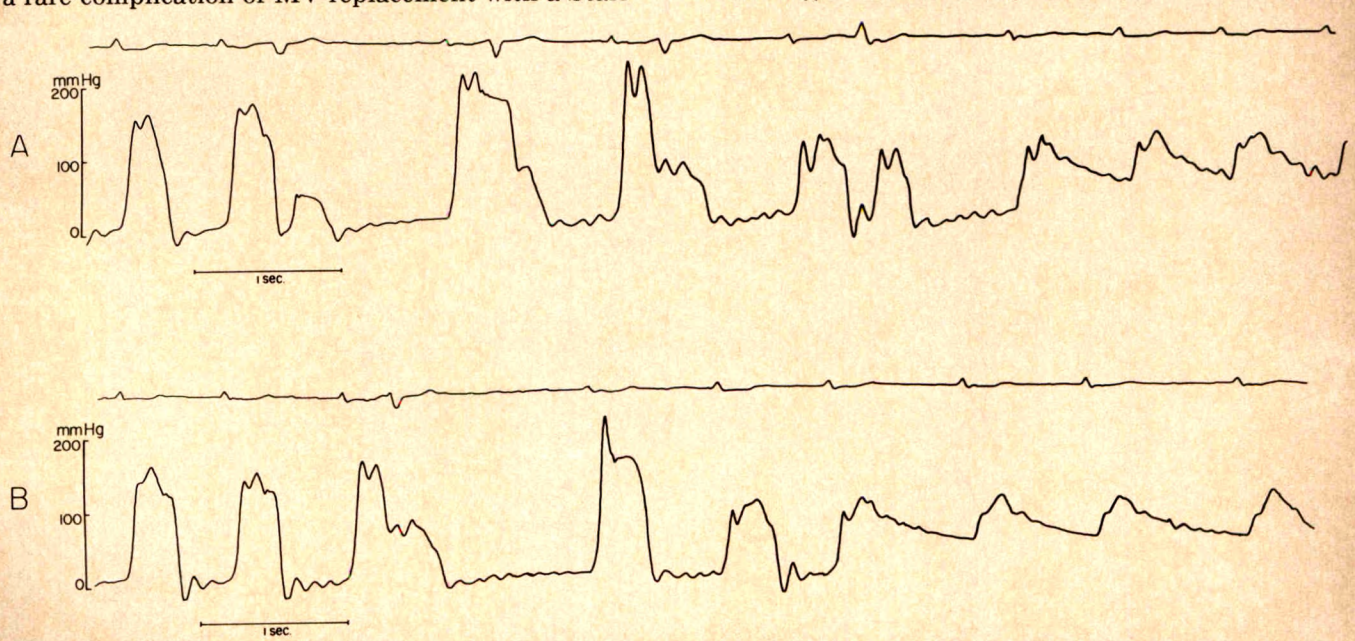

FIGURE 2. Tracings of pressures recorded on slow pullback from left ventricle to aorta with an end-hole catheter. Simultaneous ECG recordings displayed above each pressure tracing show atrial fibrillation with occasional premature beats. **A,** the last 3 beats are recorded in the aorta. The 2 beats before these are recorded in the outflow tract, with a systolic pressure equal to aortic systolic pressure, but with a diastolic pressure equal to left ventricular diastolic pressure. The seven systoles before these are recorded from the body of the left ventricle, demonstrating a systolic gradient between left ventricular body and outflow tract. **B,** the pullback sequence is repeated and demonstrates the same findings.

Cardiac Involvement by Gaucher's Disease Documented by Right Ventricular Endomyocardial Biopsy

WILLIAM D. EDWARDS, MD
HOWARD P. HURDEY III, MD
JAMES R. PARTIN, MD

We report a case in which a right ventricular endomyocardial biopsy specimen demonstrated Gaucher's cells in the myocardial interstitium. We are not aware of another instance of the biopsy diagnosis of cardiac Gaucher's disease.

A 34-year-old white woman with type 1 (chronic nonneuronopathic) Gaucher's disease had a history of splenectomy for massive splenomegaly, progressive hepatomegaly, recurrent myalgias and bone pain, and bilateral hip replacement for aseptic necrosis of the femoral heads. Unexplained systemic hypertension (150 to 195/95 to 115 mmHg), exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea and recurrent chest discomfort developed. An extensive noninvasive clinical workup failed to reveal the cause of her persistent hypertension. Cardiac catheterization, coronary arteriography and left ventriculography also failed to disclose a cause for the hypertension and cardiac symptoms. Multiple right ventricular endomyocardial biopsy specimens were procured. The patient's hypertension subsequently responded to medications, and she has since had no cardiopulmonary symptoms.

By light microscopy, the endomyocardial biopsy tissue revealed a normal endocardium and moderately hypertrophied myocardial cells. The myocardial interstitium was expanded by focal clusters of typical Gaucher's cells, which had blue-gray cytoplasm with routine hematoxylin-eosin staining and classic cytoplasmic striations with the periodic acid-Schiff base reaction and diastase predigestion (Fig. 1, A and B). By transmission electron microscopy, interstitial Gaucher's cells were distended by ellipsoid and needle-shaped membrane-bound lysosomal cytoplasmic sacs that contained twisted and filamentous deposits in a granular matrix (Fig. 1, C and D).

From the Mayo Clinic and Mayo Foundation, Rochester, Minnesota, and Cardiology Associates of Lubbock, P.A., Lubbock, Texas. Manuscript received May 9, 1983; accepted May 10, 1983.

Gaucher's disease is associated with storage of the sphingolipid glucocerebroside within the phagocytes of the reticuloendothelial system.[1,2] Involvement of the central nervous system forms the basis for 3 clinical subgroups (chronic nonneuronopathic, acute neuronopathic and subacute neuronopathic).[3] A bleeding disorder is often observed.[1] Furthermore, Gaucher's disease may involve the kidneys, lungs and heart, although cardiac involvement is usually manifested as hemorrhagic pericarditis.[4] Nevertheless, Gaucher's cells have been identified in the myocardial interstitium in autopsy specimens and, in 1 case, involved the left ventricle more extensively than the right ventricle.[4]

We report the right ventricular endomyocardial biopsy features in a woman with Gaucher's disease and unexplained hypertension, dyspnea and chest discomfort. Typical Gaucher's cells were identified in the myocardial interstitium but were not considered responsible for this patient's cardiac symptoms. Nevertheless, because endomyocardial biopsy is a safe and well-established clinical procedure that is ideally suited for the evaluation of storage diseases,[5] it may be indicated in patients with Gaucher's disease who have cardiac symptoms of undetermined cause.

The AFORMED Phenomenon: A Proposed Etiology

P. SYAMASUNDAR RAO, MD
MOHINDER K. THAPAR, MD

The alternating failure of response of mechanical to electrical depolarization (AFORMED) phenomenon was first described >10 years ago.[1] Although the physiologic effects and clinical significance of electromechanical dissociation have been studied, the cause of the phenomenon has not been investigated. This report describes our observations, which may help elucidate the etiology of this phenomenon.

We observed the AFORMED phenomenon in 3 open-chest mongrel dogs during experiments unrelated to this phenomenon. In these experiments, 20- to 25-kg dogs were anesthetized with sodium pentobarbital, cuffed endotracheal tubes were inserted, and the dogs were placed on a positive-pressure, volume-regulated Harvard respirator. The lungs were periodically hyperinflated to prevent atelectasis. The chest was opened through a median sternotomy. A fluid-filled NIH catheter was placed in the ascending aorta by retrograde arterial catheterization of the femoral artery. A Carolina Medical Electronics perivascular flow probe was positioned around the pulmonary artery to measure the pulmonary artery flow. A Millar Micro-tip pressure transducer (model PC-761) was inserted into the pulmonary trunk through a stab incision in right ventricular outflow tract for continuous recording of pulmonary artery pressure. Hypoxemia was induced by administering 14% oxygen and the effects of various receptor blockers were studied to elucidate the mechanism of hypoxic pulmonary hypertension. Each AFORMED episode occurred during the tachycardia phase that followed successful resuscitation of cardiac arrest. (Cardiac arrest occurred in some dogs during hypoxic phase of the experiment.) The electrocardiogram, aortic pressure and pulmonary artery flow were recorded continuously during the AFORMED episodes. Rapid intravenous administration of 2.0 ml of 10% calcium gluconate promptly abolished the AFORMED phenomenon, but it reappeared 10 to 15 minutes later. There was a consistent but short-lived response to calcium in each dog and in each episode of the AFORMED phenomenon. Intravenous lanatoside-C abolished the phenomenon after a 30-minute latent period. There were no recurrences of AFORMED after administering lanatoside-C during a 2- to 3-hour observation period in 2 dogs. When a faster-acting glycoside (*G. strophanthin*) was used in another dog, the AFORMED phenomenon was promptly abolished (Fig. 1). These observations suggest that the lack of availability of calcium, perhaps in the area of myofilament, is the cause of this phenomenon. The rationale for this is that the phenomenon could be abolished by increasing the calcium concentration or by augmenting the calcium influx[2] by the use of cardiac glycoside. Detailed studies of the ionic fluxes may clarify the role of calcium in the AFORMED phenomenon.

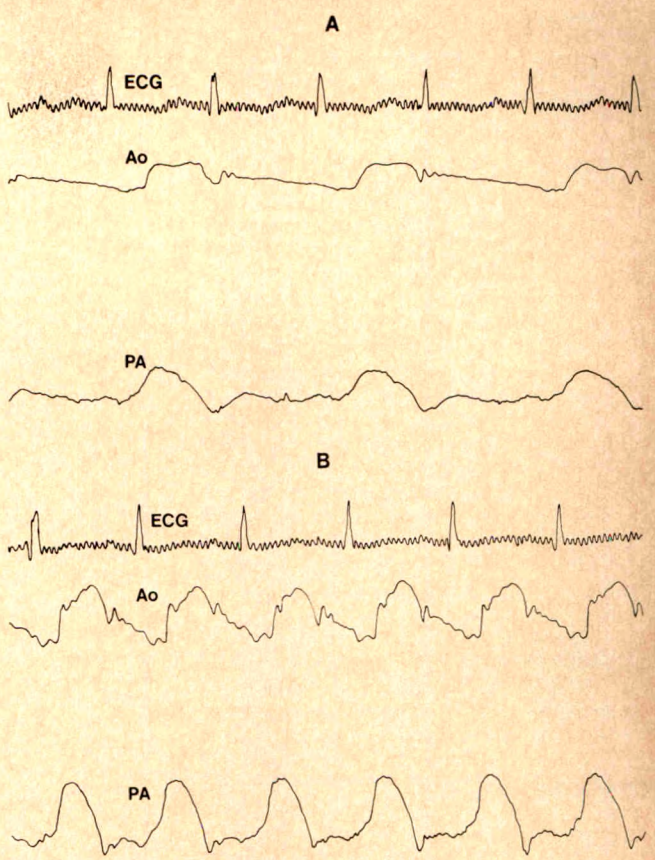

FIGURE 1. **A,** the aortic (Ao) pressure pulse follows every other QRS complex of the electrocardiogram (ECG). The pulmonary artery (PA) flow recording is also similar to aortic pressure response. This was recorded shortly after successful resuscitation of cardiac arrest. **B,** immediately after intravenous injection of *G. strophanthin*, the AFORMED phenomenon was abolished.

CARDIAC CATHETERIZATION IN ATHLETES

In the recent article by Oakley and Oakley,[1] the investigators concluded that exercise electrocardiography and echocardiography help to exclude organic heart disease, but left-heart catheterization is justified if doubt still exists.

Surprisingly, they did not even mention the role of nuclear cardiology or 2-dimensional echocardiography, especially since 6 of the 10 subjects were asymptomatic and achieved heart rates >150 beats/min. Cardiac catheterization was indicated in the subject who showed anterior Q waves and had palpitations.

Patterson et al[2] concluded that coronary angiography is not necessary to rule out the diagnosis of coronary artery disease in persons who have the 4 characteristics: (1) no clinical indicators of coronary disease, such as angina; (2) adequate exercise; (3) negative exercise electrocardiogram; and (4) negative exercise thallium images.

The addition of thallium to exercise electrocardiogram in Oakley and Oakley's patient's population would probably have eliminated the necessity of cardiac catheterization.

MULTIPLE VERSUS SINGLE CORONARY ARTERIAL STENOSIS: HEMODYNAMIC DIFFERENCES

The study by Subbah and Stein points out 1 difficulty in evaluating hemodynamic severity of coronary artery stenoses if only the percentage of coronary diameter reduction is used.[1] Their study shows in an in vitro system how multiple coronary stenoses in 1 vessel can have a greater effect on coronary flow than a single stenosis of equal diameter reduction and length. The authors also found that lengthening a 50% coronary diameter reduction from 2–6 mm had little effect on the magnitude of coronary flow reduction. This last point seems to be in slight discrepancy with our findings.[2–4]

We found in dogs that lengthening coronary stenoses of 40 to 60% diameter reduction does affect coronary flow. These effects were most pronounced during coronary vasodilation occurring after transient coronary occlusion. In their in vitro system, Sabbah and Stein did not find increasing the length of a 50% stenosis by a factor of 3 produced important changes. In open-chest dogs, we found during vasodilation a 9% decrease in flow as the length of 40–60% coronary stenoses were increased from 1 to 3 mm. More prominent effects on coronary flow were seen as narrowing length was increased from 5 to 15 times (i.e., from 1 to 5, 10 to 15 mm) both during vasodilation and at rest. These findings agree with those of Friesinger and Hillis,[5] who also evaluated in an in vivo model the effect of longer stenoses than did Sabbah and Stein. Therefore, the differences observed concerning the importance of coronary stenoses length may be because of the longer lengths (i.e., up to 10 and 15 mm) and relative change in stenosis length (i.e., by factors of 2, 3, 5, 10 and 15) we used.

We also studied the effects of multiple coronary stenoses on 1 vessel and compared them to single stenoses of similar total length in open-chest dogs.[3,4] Our in vivo results were similar to the in vitro findings of Sabbah and Stein. We found that 40–60% diameter reductions 2–3 mm long did not reduce resting flow or increase the pressure gradient across them. Multiple 1-mm-long stenoses consistently produced small resting pressure gradients. Additionally, during vasodilation produced by transient coronary occlusion, 2 or 3 stenoses decreased coronary flow more than 1 stenosis of similar total length.

BASIC REQUIREMENTS FOR INVESTIGATING SYSTOLIC TIME INTERVALS

Carroll et al[1] have contributed an outstanding report on serial changes in left ventricular (LV) function after correction of chronic aortic regurgitation. As with most letters to the editor, this is not so much to criticize the authors' work so much as the review process ("revision accepted" implies eagle-eyed reviews). Here, reviewers familiar with systolic time intervals should have caught 2 important methodologic omissions: heart rate (HR) influence, particularly correction of the preejection period (PEP) and other systolic intervals (STIs), and consideration of the patients' therapeutic status.

Considerable "standard" literature insists on the necessity to rate-corrected PEP. Yet, a great deal of work (summarized in references 2 to 4) indicates that PEP is either negligibly related to HR or, at best, related with very low correlation coefficients of borderline significance. Regardless of the levels of correlation, many workers consider that failure of PEP to change during atrial pacing—virtually "pure" HR effect—makes even statistically significant HR-PEP associations physiologically spurious. (Pacing does reduce LV ejection time [LVET] and, consequently, QS_2.) In fairness, those working in the field have not come to a consensus; moreover, correction factors (slope of the linear regression) for ejection time and QS_2 are not the same for all investigators. Thus, in every report of STIs it is methodologically necessary to insist on including HR data. This permits those who differ on these points to recalculate the results and examine them in the light of their own results and conceptual preferences. I should like to ask the authors to provide the HRs corresponding to their data in their Table III. Finally, and in fairness, I have observed that when PEP is used without rate correction, directional results are almost always the same as when some rate correction ("PEP index") is used, although significance levels may differ owing to contribution by larger or smaller HR and, presumably, departures from linearity. This observation may explain why no strong effort has been made to resolve the appropriateness of PEP "correction" for HR.

Another inescapable consideration is the patients' therapeutic status. STIs are sensitive to a wide variety of pharmacologic agents. Some of these patients may have been taking digitalis, which variably shortens the STI. Therefore, mention should be made of the patients' medication in each group and whether results differed within a given group for those taking digitalis or any other agent that affects the STI.

Your patients deserve the best ECG analysis they can get.

Yours.

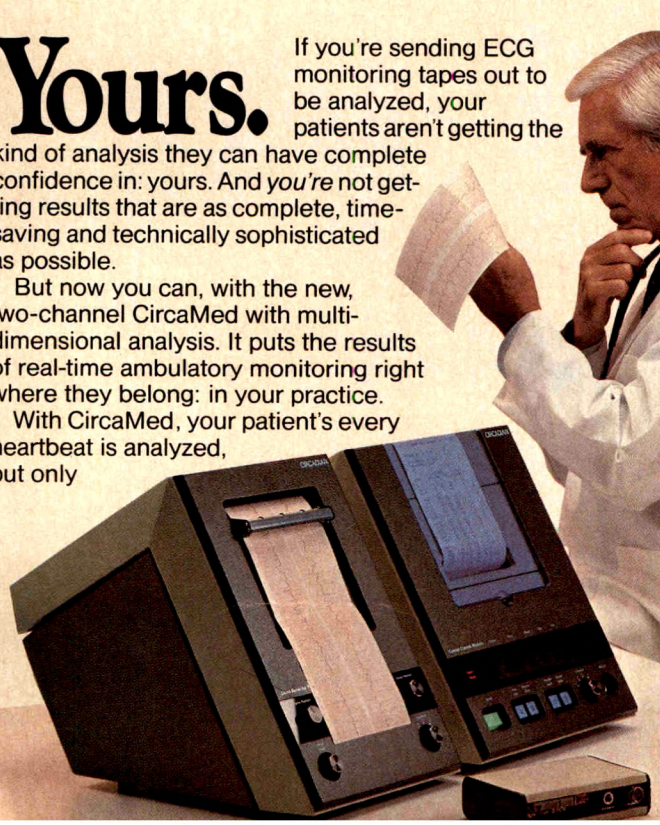
If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.

That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.



CIRCADIAN

Leaders in real-time ECG analysis.

To contain the risk of life-threatening V-Fib in the patient with serious V-Tach

Bretylol® (bretylium tosylate)

Electrical instability often underlies hemodynamically unstable V-Tach, breakthrough V-Tach, and recurrent V-Tach. This hidden instability carries with it the danger of life-threatening V-Fib.

Because you know V-Tach is often the precursor of ventricular fibrillation...

Use Bretylol to get added *insurance against* and *continued protection from* the underlying electrical instability which can lead to V-Fib.

Bretylol provides unique antifibrillatory action

- ***Bretylol suppresses reentry*** **by helping to equalize the electrophysiological differences between injured and normal ventricular muscle.**[1,2*]
- ***Bretylol raises the V-Fib threshold*** **almost three times control level.**[3*]
- ***Bretylol*** **also *reduces the energy required for defibrillation* by as much as one-third.**[4,5*]

*Based on laboratory animal studies.

© 1983 American Critical Care
Division of American Hospital Supply Corporation

Bretylol is indicated for first-line treatment of V-Fib and for protection against V-Fib. In patients with life-threatening ventricular arrhythmias other than V-Fib and not at risk of V-Fib, Bretylol is indicated if the arrhythmia has failed to respond to adequate doses of a first-line agent such as lidocaine.

The most common side effect of Bretylol is postural hypotension. Some degree of hypotension is present in approximately 50 percent of patients while they are supine. Please see following page for a brief summary of the prescribing information.

For further information please contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 800/323-4980.

American Critical Care

Bretylol®
(bretylium tosylate)

Brief summary of prescribing information

INDICATIONS—BRETYLOL is indicated in the prophylaxis and therapy of ventricular fibrillation.

BRETYLOL is also indicated in the treatment of life-threatening ventricular arrhythmias, such as ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrhythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS—**1. Hypotension:** Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, lightheadedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

> Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

2. Transient Hypertension and Increased Frequency of Arrhythmias: Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

3. Caution During Use with Digitalis Glycosides: The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL (bretylium tosylate) should be avoided.

4. Patients with Fixed Cardiac Output: In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY—The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

USE IN CHILDREN—The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

PRECAUTIONS—**1. Dilution for Intravenous Use:** BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

2. Use of Various Sites for Intramuscular Injection: When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

3. Reduce Dosage in Impaired Renal Function: Since BRETYLOL is excreted principally via the kidney, the dosage interval should be increased in patients with impaired renal function.

ADVERSE REACTIONS—Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

HOW SUPPLIED—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP. pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, non-pyrogenic.

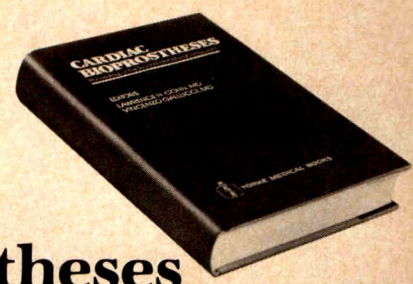
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

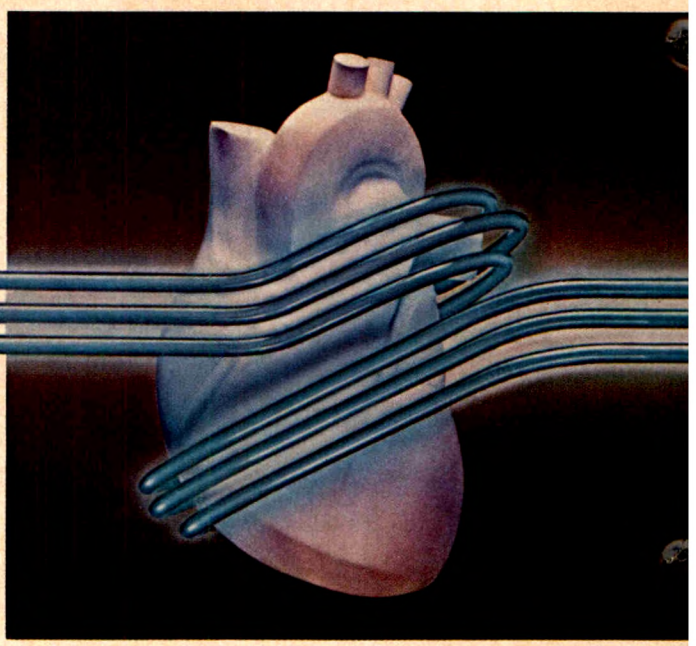
ANGINA PROTECTION AND MORE

—WITH SIMPLE, ONCE-DAILY DOSAGE

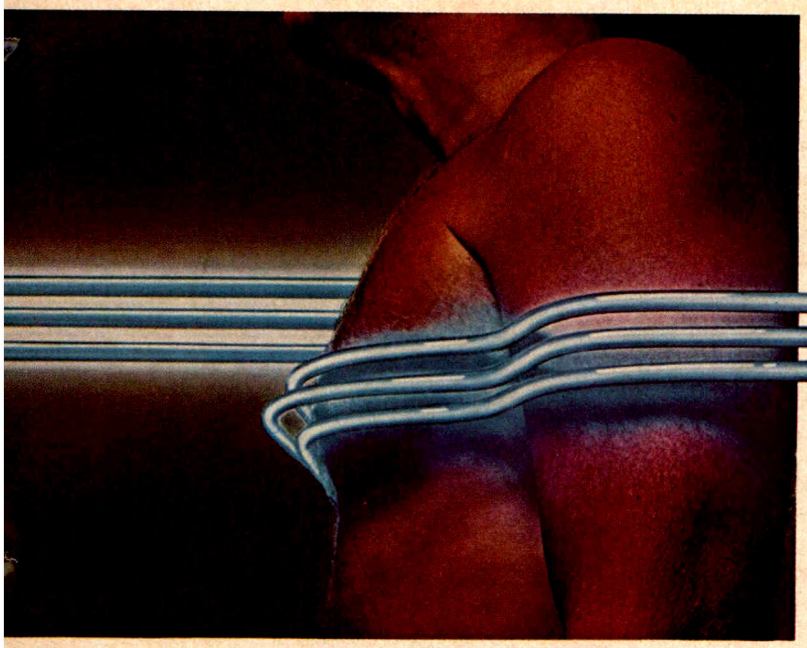


The cardiovascular protection of INDERAL—for simplified core therapy in angina

Once-daily INDERAL LA (propranolol HCl) adds simplicity and convenience to the therapeutic benefits of INDERAL in the long-term treatment of angina.

INDERAL LA provides smooth, 24-hour beta blockade with single daily dosing–to reduce the frequency and severity of anginal attacks around the clock. As core therapy, INDERAL LA is compatible with other conventional antianginal therapies.

Like INDERAL tablets, INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, heart block greater than first degree, or bronchial asthma.



THE ONE™ TO COUNT ON

Start with 80 mg once daily...

Simplified core therapy begins with 80 mg once daily. Although individual patients may respond to various doses, the average optimal dose in angina pectoris is 160 mg once daily.

When converting patients from other beta blockers, including INDERAL tablets, switch to the nearest milligram equivalent of INDERAL LA once daily and evaluate clinical results to determine if dosage adjustment is necessary. For arrhythmias, use conventional INDERAL (propranolol HCl) tablets.

80 mg 120 mg 160 mg

The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

Please see next page for brief summary of prescribing information.

ONCE-DAILY

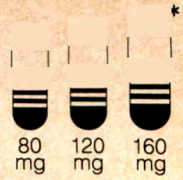
INDERAL® LA

(PROPRANOLOL HCl) LONG ACTING CAPSULES

Ayerst®

The one to count on for ANGINA, HYPERTENSION and prevention of MIGRAINE.

ONCE-DAILY INDERAL® LA (PROPRANOLOL HCl) LONG ACTING CAPSULES



BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION SEE PACKAGE CIRCULAR.)*
INDERAL® LA BRAND OF propranolol hydrochloride
(Long Acting Capsules)
DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg, and 160 mg capsules.
CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta-blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the pial vessels of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.
INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.
CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.
WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.
PRECAUTIONS. General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.
DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE — At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

*The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

When diet fails in NIDDM
Insulin...

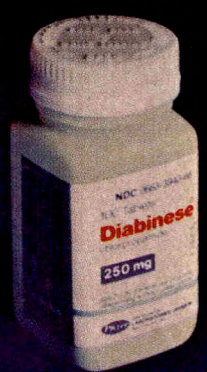
or once-a-day Diabinese®? (chlorpropamide)

For many Non-Insulin-Dependent Diabetics, an effective, convenient alternative to low-dose insulin (<40 units per day).

Insulin therapy lowers blood sugar. But injections can be uncomfortable and inconvenient.

Diabinese, the most widely prescribed oral agent, can effectively lower blood glucose for many NIDDM patients. And by avoiding the inconvenience of injections, Diabinese therapy encourages compliance. So, Diabinese may be a logical alternative for NIDDM patients requiring less than 40 units of insulin per day.*

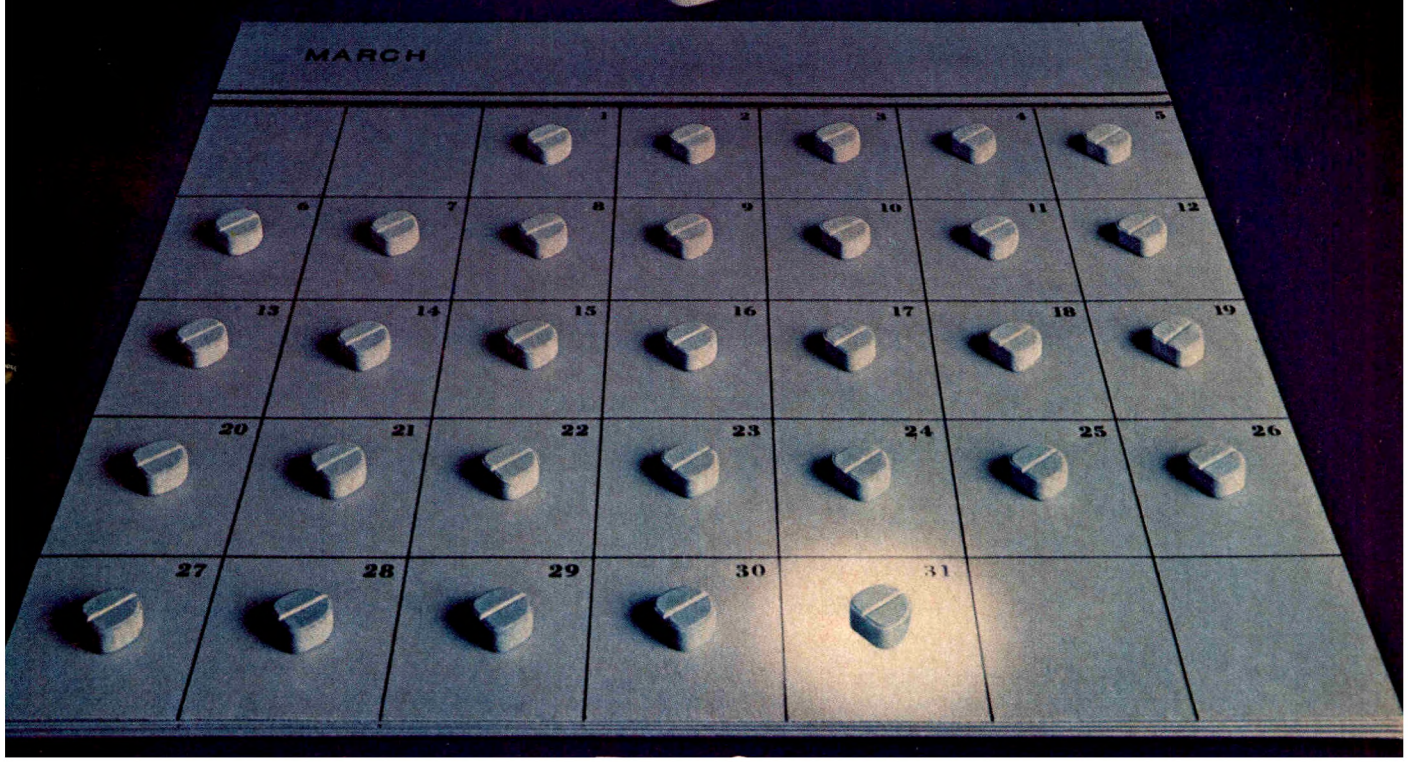
Diabinese, the distinctive blue D-shaped chlorpropamide tablet from Pfizer Laboratories, is the only oral antidiabetic agent with once-a-day convenience, regardless of dosage. And, it is economical.



When choosing a therapeutic regimen to treat Non-Insulin-Dependent Diabetes Mellitus (NIDDM), many factors should be considered, including the patient's age, mental state, concomitant medication, and illnesses.

*As with all sulfonylureas, hypoglycemia may occur with Diabinese, but less frequently than with insulin therapy.

Pfizer LABORATORIES DIVISION
PFIZER INC
Leaders in Oral Diabetic Therapy



Diet & Diabinese®
(chlorpropamide) Tablets 100 mg and 250 mg

A proven regimen for effective control of blood sugar.

BRIEF SUMMARY
DIABINESE® (chlorpropamide) Tablets

Contraindications: Diabinese is not indicated in patients having juvenile or growth-onset diabetes mellitus, severe or unstable "brittle" diabetes, and diabetes complicated by ketosis and acidosis, diabetic coma, major surgery, severe infection, or severe trauma. Diabinese is contraindicated during pregnancy. Serious consideration should be given to the potential hazard of its use in women of childbearing age who may become pregnant.
Diabinese is contraindicated in patients with serious impairment of hepatic, renal, or thyroid function.
Precautions: Use chlorpropamide with caution with barbiturates, in patients with Addison's disease or in those ingesting: alcohol, antibacterial sulfonamides, thiazides, phenylbutazone, salicylates, probenecid, dicoumarol or MAO inhibitors. Adequate dietary intake should be assured in all patients using Diabinese.
Warnings: DIABINESE (CHLORPROPAMIDE) SHOULD NOT BE USED IN JUVENILE DIABETES OR IN DIABETES COMPLICATED BY ACIDOSIS, COMA, SEVERE INFECTION, MAJOR SURGICAL PROCEDURES, SEVERE TRAUMA, SEVERE DIARRHEA, NAUSEA AND VOMITING, ETC. HERE, INSULIN IS INDISPENSABLE.
HYPOGLYCEMIA, IF IT OCCURS, MAY BE PROLONGED. (SEE ADVERSE REACTIONS.) IN INSTANCES OF CONCOMITANT USE WITH INSULIN, PATIENTS SHOULD BE CAREFULLY MONITORED.
Adverse Reactions: Usually dose-related and generally respond to reduction or withdrawal of therapy. Generally transient and not of a serious nature and include anorexia, nausea, vomiting and gastrointestinal intolerance; weakness and paresthesias.
Certain untoward reactions associated with idiosyncrasy or hypersensitivity have occasionally occurred, including jaundice, skin eruptions rarely progressing to erythema multiforme and exfoliative dermatitis, and probably depression of formed elements of the blood. They occur characteristically during the first six weeks of therapy. With a few exceptions, these manifestations have been mild and readily reversible on the withdrawal of the drug. The more severe manifestations may require other therapeutic measures, including corticosteroid therapy. Diabinese should be discontinued promptly when the development of sensitivity is suspected.
Jaundice has been reported, and is usually promptly reversible on discontinuance of therapy. THE OCCURRENCE OF PROGRESSIVE ALKALINE PHOSPHATASE ELEVATION SHOULD SUGGEST THE POSSIBILITY OF INCIPIENT JAUNDICE AND CONSTITUTES AN INDICATION FOR WITHDRAWAL OF THE DRUG.
Leukopenia, thrombocytopenia and mild anemia, which occur occasionally, are generally benign and revert to normal, following cessation of the drug.
Cases of aplastic anemia and agranulocytosis, generally similar to blood dyscrasias associated with other sulfonylureas, have been reported.
BECAUSE OF THE PROLONGED HYPOGLYCEMIC ACTION OF DIABINESE, PATIENTS WHO BECOME HYPOGLYCEMIC DURING THERAPY WITH THIS DRUG REQUIRE CLOSE SUPERVISION FOR A MINIMUM PERIOD OF 3 TO 5 DAYS, during which time frequent feedings or glucose administration are essential. The anorectic patient or the profoundly hypoglycemic patient should be hospitalized.
Rare cases of phototoxic reactions have been reported.
Edema associated with hyponatremia has been infrequently reported. It is usually readily reversible when medication is discontinued.
Dosage: The total daily dosage is generally taken at a single time each morning with breakfast. Occasionally, cases of gastrointestinal intolerance may be relieved by dividing the daily dosage. A LOADING OR PRIMING DOSE IS NOT NECESSARY AND SHOULD NOT BE USED. The mild to moderately severe, middle-aged, stable diabetic should be started on 250 mg daily. Because the geriatric diabetic patient appears to be more sensitive to the hypoglycemic effect of sulfonylurea drugs, older patients should be started on smaller amounts of Diabinese, in the range of 100 to 125 mg daily.
After five to seven days following initiation of therapy, dosage may be adjusted upward or downward in increments of 50 to 125 mg at intervals of three to five days. PATIENTS WHO DO NOT RESPOND COMPLETELY TO 500 MG DAILY WILL USUALLY NOT RESPOND TO HIGHER DOSES. Maintenance doses above 750 mg daily should be avoided.
Supply: 100 mg and 250 mg, blue, 'D'-shaped, scored tablets.

More detailed professional information available on request.

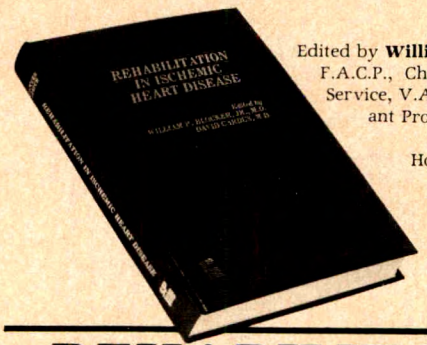
This book contains the most complete list of cardiac risk factors to be found in any text. . .



Edited by **William P. Blocker, Jr., M.D.,** F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine, Baylor College of Medicine, Houston, and **David Cardus**, M.D., F.A.C.C., Professor of Physiology and Rehabilitation, Baylor College of Medicine, Houston, Texas.

REHABILITATION IN ISCHEMIC HEART DISEASE

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

Approx. 500 pp., 188 figs. & tbls., large format 8½x11, 1982, $80.00

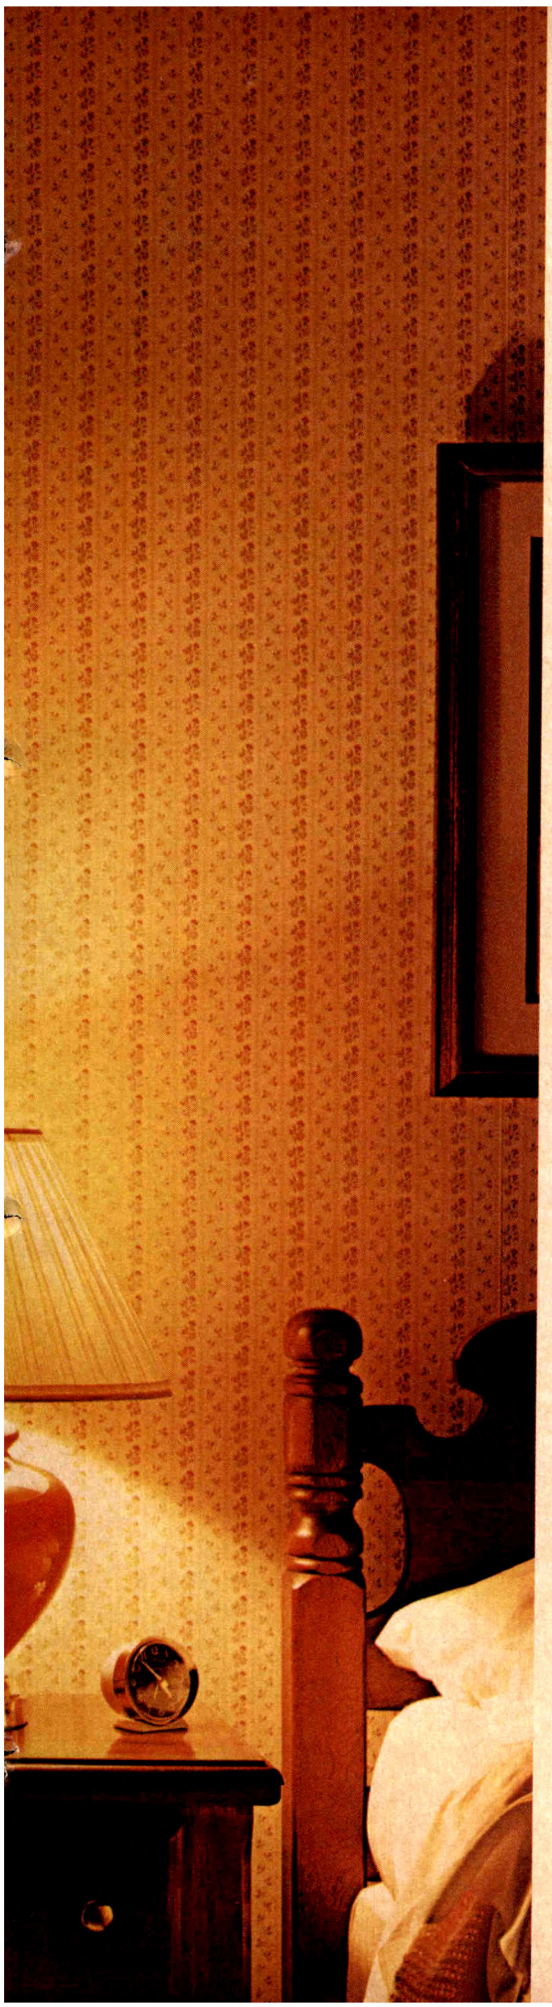
Predawn anginal attacks–
A sign that long-acting oral nitrates may no longer be acting



24-hour

Transderm®-Nitro

nitroglycerin

Helps protect your patients with angina all day, all night

Transderm-Nitro is longer acting, more convenient than oral nitrate capsules and tablets. One simple 10-second application provides steady-state drug delivery to assure a full 24 hours of consistent, appropriate blood levels. No therapeutic peaks and valleys that can occur with oral dosage forms. 2.5 mg/24 hr, 5 mg/24 hr, 10 mg/24 hr, and 15 mg/24 hr strengths.

Side effects include transient headaches and orthostatic hypotension.
Contraindicated in patients with increased intraocular pressure. Withdrawal from treatment should be gradual.

Please read Brief Summary of Prescribing Information.

C I B A

First with the future in drug delivery systems

24-hour
Transderm®-Nitro
nitroglycerin

Helps protect your angina patients all day, all night.

Transderm®-Nitro nitroglycerin Transdermal Therapeutic System

Brief Summary of Prescribing Information.

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

Consult complete product information before prescribing.

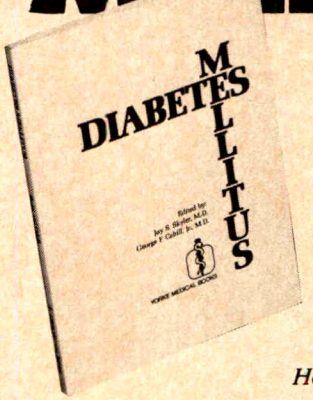
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes. Featured topics include:

- The causes of diabetic inheritance
- Mechanisms of diabetes
- New developments in the treatment of diabetes
- Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

DIFFERENT DOCTORS, DIFFERENT PATIENTS, ONE SYSTEM.

Don't compromise. With System Q from Quinton, you can test the way you want to test. And so can every doctor who works with you.

It adapts. So you don't have to.

State-of-the-art microprocessor technology gives System Q the power to adapt to your individual testing requirements. The Q2000 monitor can store up to five programmed test procedures, each customized to meet the specific needs of a different physician.

It adapts to your patients, too. You can modify your procedure for a single test, with flexible control over 17 elements of the test, from ST sample point to treadmill protocol.

A superior diagnostic tool.

The Q2000 gives you more data, more accurately than ever before possible. Its averaged beat final report, with computed ST parameters, gives you more usable ECG information. Its QRS detection algorithms are the most sophisticated ever developed. It offers you a more precise calculation of ST parameters. And a more stable heart rate indication.

Stress testing simplified.

The most advanced stress test system ever built is also the simplest to use. You can learn to operate System Q in a few minutes. And learn to program it in less than an hour.

A new standard for treadmills.

No treadmill has ever been quieter. Or more functional. Quinton's Q55 is the state-of-the-art.

Its sleek, low-profile design with wider walking surface improves patient safety and gives the subject more room to maneuver. The transmission was Quinton-engineered to offer quieter overall performance. Larger drums provide improved tracking. And a self-leveling feature makes it solid as a rock.

SYSTEM Q.

Engineered to be a workhorse.

System Q offers one specification you won't find on other stress test systems: Quinton reliability. It was engineered to work, day in and day out. To meet the changing demands of different doctors. To test more people with greater reliability.

It could be working for you (for less than you'd expect). Find out more. Call or write Quinton Instrument Company, 2121 Terry Ave., Seattle, WA, 98121, 1-800-426-0347, Telex 328840.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreas excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digox (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases whe the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: Th drug should be used with caution due to excretion of the quinidine in breast milk. ADVERS REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/ disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTES TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QR complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricul tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMA TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranul cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, an syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasi blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, nig blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intens pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episod vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribin Information.

SYMPOSIUM ON PERSPECTIVES ON THE TREATMENT OF VENTRICULAR ARRHYTHMIAS

1C Introduction

DONALD C. HARRISON

3C Importance of Metabolites in Antiarrhythmic Therapy

RAYMOND L. WOOSLEY and DAN M. RODEN

Metabolites of antiarrhythmic drugs are frequently important for their action and toxicity. The presence of active metabolites can be inferred from variability of response to steady-state therapeutic plasma concentrations. In some cases, metabolites may accumulate to toxic levels during heart, renal or hepatic failure. Therefore, direct evaluation of metabolites is indicated when they are known. Procainamide, quinidine, disopyramide, verapamil, encainide and lorcainide are drugs whose metabolites are under study.

8C Plasma Level Monitoring of Antiarrhythmic Drugs

ROBERT E. KATES

Therapeutic plasma concentration guidelines have been proposed for most antiarrhythmic drugs. The relation between measured plasma concentration and effect is well characterized for only a few drugs, and it is recognized that several factors influence this relation. These factors include serum protein binding, active metabolites, intrinsic responsiveness and myocardial accumulation. Interpretation of plasma concentration of antiarrhythmic drugs also requires consideration of pharmacokinetic factors. Plasma drug levels can be useful only when dosing history and timing of the sample relative to drug administration are considered. Despite several limitations, plasma concentration monitoring of antiarrhythmic drugs can be helpful if evaluated with an understanding of the pharmacokinetics of the drug being measured, the clinical status of the patient, and an appreciation of the factors that may influence the relation between the measured level and the resultant clinical response.

14C Hemodynamic Effects of Antiarrhythmic Drugs

PAUL J. BLOCK and ROGER A. WINKLE

It is important to understand the hemodynamic effects of the antiarrhythmic drugs in order to use them safely. Many of these drugs have a direct effect on myocardial performance as well as on the peripheral capacitance and resistance vessels. The net effect of a drug often depends on the balance between these direct actions and reflex and other autonomically mediated drug effects. This report reviews the in vitro and in vivo hemodynamic data available for each of the frequently used antiarrhythmic drugs. These data and their clinical implications are discussed.

24C Clinical Profiles of Newer Class I Antiarrhythmic Agents—Tocainide, Mexiletine, Encainide, Flecainide and Lorcainide

ANTHONY POTTAGE

Potency is only 1 factor that determines the clinical value of an antiarrhythmic agent. Electrophysiologic and hemodynamic effects that compromise safety are clearly undesirable, as are other adverse effects that limit safety or patient acceptability. Pharmacokinetic properties that allow various routes of administration and predictable

behavior in a broad spectrum of patients are an advantage. New class I antiarrhythmics—tocainide, mexiletine, encainide, flecainide and lorcainide—have been developed in a search for increased potency, fewer cardiac and noncardiac adverse effects, and pharmacokinetics that allow greater flexibility of use. Some are remarkably effective for short-term use and are virtually free of dose-related adverse effects. Others have pharmacokinetic properties that allow predictable use in a variety of clinical settings. Although none of the newer agents reliably suppresses all arrhythmias in all patients, their differing electrophysiologic effects and pharmacokinetic properties extend the range of options available for individualization of therapy in the patient at risk.

32C Effect of Antiarrhythmic Drugs on Mortality After Myocardial Infarction

CURT D. FURBERG

Antiarrhythmic drugs have theoretical potential for prevention and prophylaxis of ventricular arrhythmias in patients with coronary heart disease. However, randomized, controlled clinical trials have not demonstrated conclusive effects on survival. This may be because they do not improve prognosis, because insufficient design methods obscure a favorable intervention effect which does occur, or because drugs help some patients while harming others and thereby confound the results. Of 20 clinical trials, ventricular arrhythmia as an entry criterion occurred in only 1; all trials were small. Increasing attention to methods will permit better-designed trials.

37C Methods for Documenting Antiarrhythmic Efficacy

DONALD C. HARRISON

Although several methods have been suggested for demonstrating the efficacy of antiarrhythmic agents, no single method has been fully accepted by clinical investigators. Spontaneous variability in the occurrence of arrhythmias in individual patients makes assessment of individual response difficult, but the relative comparability of average frequency and complexity within groups presents investigators with an opportunity to determine, over time, an average response. Establishing expected responses and variations from that with confidence intervals by a new statistical approach using linear regression analysis appears promising. Continued research for establishing widely acceptable methods is required.

41C Role of Electrophysiologic Techniques in the Selection of Antiarrhythmic Drug Regimens for Ventricular Arrhythmias

JEREMY N. RUSKIN, MARK H. SCHOENFELD, and HASAN GARAN

Programmed electrical stimulation of the heart provides a useful new technique for guiding the selection of antiarrhythmic drug regimens in selected patients with ventricular tachycardia (VT) or ventricular fibrillation. The technique of programmed electrical stimulation has been applied successfully in patients with recurrent sustained VT, out-of-hospital ventricular fibrillation and unexplained syncope in the presence of structural heart disease. The complete suppression with a drug regimen of VT induced by programmed electrical stimulation is highly predictive of freedom from both recurrent VT and sudden death. In addition, this technique appears to hold promise as a means of assessing the arrhythmogenic effects of antiarrhythmic drugs in selected patients.

47C Definition of Benign Versus Malignant Ventricular Arrhythmias: Targets for Treatment

J. THOMAS BIGGER, Jr.

The prevalence and clinical significance of ventricular arrhythmias determine their need for treatment. The clinical significance is greater with advancing age, severity of heart disease and ventricular hypertrophy. The most malignant arrhythmias are out-of-hospital ventricular fibrillation, recurrent sustained ventricular tachycardia, and torsades de pointes ventricular tachycardia. Potentially malignant arrhythmias are well defined only in the post–myocardial infarction patients. In these patients, ventricular premature complexes have independent prognostic significance when they are more frequent than 10 per hour. Benign ventricular arrhythmias are common in patients with no heart disease.

55C Treatment and Prophylaxis of Ventricular Arrhythmias in Acute Myocardial Infarction

RONALD W. F. CAMPBELL

Antiarrhythmic drug use in acute myocardial infarction has undergone major changes in the last 20 years. Selective and unselective prophylactic drug administration and drug use only for established life-threatening arrhythmias are the 3 major strategies in current use. Each has limitations and none is ideal. New evidence regarding the natural history of arrhythmias during the coronary care unit phase of infarction suggests that reappraisal of the goals of electrocardiographic monitoring is required. Further research and investigation of arrhythmia management in the acute phase of myocardial infarction is hampered by ethical and scientific considerations but is sufficiently important to warrant finding ways to perform new studies.

Symposium on Perspectives on the Treatment of Ventricular Arrhythmias

Donald C. Harrison, Guest Editor

Introduction

DONALD C. HARRISON, MD

This symposium contains presentations made by a distinguished faculty at a symposium entitled, "Perspectives on the Treatment of Ventricular Arrhythmias," held March 19, 1983, in New Orleans, Louisiana. A group of experts was assembled to present the new and exciting work that is taking place. The meeting and the publication of the reports presented are supported by an educational grant from Merck Sharp & Dohme.

The objectives and goals for the symposium included presenting the state-of-the-art methods for treating ventricular arrhythmias, focusing on coupling basic science with clinical applications, and the diagnosis, classification and treatment of this common malady affecting patients with heart disease. The pharmacodynamic and pharmacokinetic profile of existing drugs and newer antiarrhythmic drugs were the focus of several presentations. In addition, 2 speakers identified the patients with ventricular arrhythmias who could not be treated. Finally, it was our purpose to provide study designs for assessing the efficacy and safety of the new agents that are being introduced on an almost daily basis.

Clinical Background

Cardiovascular disease killed more than 1 million persons in the United States last year. This represented 51% of all deaths; of these, approximately 350,000 patients experienced sudden cardiac death, which the evidence to date suggests was due to ventricular arrhythmias. In recent years, the number of patients with serious ventricular arrhythmias seen by cardiologists appears to be increasing. The reasons for this increase are unclear, but may relate to 4 factors. First, monitoring techniques are available for the detection of arrhythmias in a much broader group of patients with coronary heart disease. Ambulatory monitoring, computer-based, in-hospital monitoring systems, and phone transmission of electrocardiograms all permit a higher degree of monitoring. Second, more patients with serious ventricular function are surviving myocardial infarction as a result of improved care. These persons are more prone to develop serious and life-threatening ventricular arrhythmias. Third, resuscitation of persons who experience sudden death out of the hospital is becoming much more common. These persons represent a pool of arrhythmia patients seen by the cardiologist. Fourth, patients and physicians are more aware of what I have termed "cosmetic arrhythmias," which may be noted on an electrocardiogram or an ambulatory monitoring device but do not have serious consequences or prognostic implications.

Since arrhythmias are seen with greater frequency, the public and physicians are more aware of antiarrhythmic drugs and their potential for preventing sudden cardiac death.

Modified Classification of Antiarrhythmic Agents

In the symposium, 2 factors receive serious consideration. The first is a modification of the existing classification schemes for antiarrhythmic agents. Vaughan Williams devised a 4-level classification scheme based upon cellular electrophysiologic observations. Class I agents have local anesthetic action and affect fast sodium channels; the prototypical agent is quinidine.

From the Cardiology Division, Stanford University School of Medicine, Stanford, California.

Address for reprints of this Symposium: Cardiology Division, Stanford University, California 94305.

Class II agents are beta-adrenergic blocking drugs, including selective and nonselective agents. Propranolol is generally considered the prototype agent. Class III agents are those that prolong the action potential repolarization phases. Amiodarone is usually considered the prototype for this group. Class IV drugs are calcium-channel blocking agents that have cardiac effect; verapamil is usually considered the prototype drug.

Many new agents obviously fall into the Vaughan Williams class I group. I recently devised a scheme of expanding the class I agents into subgroups. Table I is an outline of a modified class I schema based upon electrophysiologic studies in cells and in man together with a clinical profile. I believe that this modified system permits a means of thinking about the new agents we encounter.

All classification schemes are arbitrary and may be challenged. However, for ease of thinking and some practical points about combination therapy in patients, such a modified class I scheme seems useful. In treating patients with combined therapy, class Ia should be combined with class Ib, or class Ic should be combined with class Ib. Class Ia and Ic drugs probably should be given in combination only carefully.

TABLE I Modified Class I Based on Electrophysiologic and Clinical Profiles

Class	Action	Prototype Drugs
Ia	Depress phase 0 of the action potential	Quinidine
	Prolong repolarization	Procainamide
	Slow conduction, moderately	Disopyramide
Ib	Little effect on phase 0 of the action potential	Lidocaine
	Shorten repolarization	Mexiletine
	Increase fibrillation threshold	Tocainide
Ic	Markedly depress phase 0 of the action potential	Encainide
	Slight effect on repolarization	Flecainide
	Profound slowing conduction	Lorcainide

Methods of Assessing Efficacy of Antiarrhythmic Drugs

During the past several decades, considerable controversy has developed regarding the means of assessing the efficacy of antiarrhythmic drugs. There is no ideal way, but 3 subcategories of response might be considered.

First are population studies. It is frequently easy to average the response of a group of patients. This average response may be in controlled trials of the agent under study against a placebo; it may be a comparative trial of the new agent with a standard agent, or it may be in a parallel-designed field trial, with death or recurrence of serious arrhythmias as endpoints.

Second, studies may be performed in individual patients. Because of the high likelihood of spontaneous variability, determinations in an individual patient without multiple monitoring sessions are difficult. If a drug prevents arrhythmic symptoms that are closely correlated with heart disease, it may be thought of as effective. Other techniques that demonstrate the abolition of arrhythmias below 80% of a control level have also been advocated. More recently, the identification of agents that block the electrophysiologic induction of ventricular tachycardia has received widespread advocacy with the more highly refined electrophysiologic techniques. However, only a few agents prove to be effective by this means.

Third, there are some nonspecific approaches to determining efficacy. After therapeutic blood levels have been established, it is acceptable to administer the agent to produce an effective therapeutic blood level and to assume that efficacy has been achieved. It is also possible to establish the characteristics of a group of patients in a disease category by an analysis of variance, and the development of acceptable deviations from these established characteristics. Such a technique will be the subject of a report included in this symposium.

Included in the symposium are papers at the very forefront of our knowledge on arrhythmias, drugs for their treatment, and perspectives on future developments in this increasingly important field. We thank Merck Sharp & Dohme for their sponsorship of the meeting and their support for publishing this symposium.

The following abbreviations are used in the articles in this Symposium:

CAD = coronary artery disease
EF = ejection fraction
LV = left ventricular
MI = myocardial infarction
VF = ventricular fibrillation
VPC = ventricular premature complexes
VT = ventricular tachycardia

Importance of Metabolites in Antiarrhythmic Therapy

RAYMOND L. WOOSLEY, MD, PhD, and DAN M. RODEN, MD

The presence of metabolites with pharmacologic activity can produce unanticipated drug efficacy or toxicity. This is particularly true during treatment with drugs that have narrow therapeutic-toxic ratios, such as the antiarrhythmic agents. The presence of active metabolites can often be inferred from variability in the relation between pharmacologic effect and steady-state plasma concentrations of the parent drug. Moreover, metabolites may ordinarily be unimportant but can accumulate to therapeutic (or toxic) levels in disease states such as congestive heart failure, renal failure and hepatic failure. Further characterization of the contribution of such metabolites during treatment requires direct evaluation of their pharmacology in vitro, in animal models and, if indicated, in man. Procainamide and its active metabolite N-acetylprocainamide provide the best and most complete example of this sequence of observations. Other drugs, including quinidine, disopyramide, verapamil and the investigational agents encainide and lorcainide, have active metabolites for which pharmacologic activity is less well-defined. Further studies in this area will help reduce the frequency of antiarrhythmic drug adverse effects, make successful therapy more frequent, and perhaps allow insights into structure-activity relations.

(Am J Cardiol 1983;52:3C–7C).

Definition of the mechanisms of interindividual variability in drug response aims to improve therapeutics, that is, to decrease the occurrence of adverse effects and treatment failures. The selection of a drug dosage that maximizes therapeutic effects while minimizing adverse effects is particularly important for agents with low ratios between these endpoints. This requirement has provided the impetus for monitoring plasma drug concentrations in an effort to minimize interindividual variability in drug response due to differences in absorption, distribution or elimination. However, even under circumstances that produce comparable plasma drug concentrations, variability in response is still observed. There are a number of potential explanations for failure of plasma steady-state drug concentrations to correlate with pharmacologic effects, including assay nonspecificity, mediation of drug effects by the generation of ≥1 active metabolites, persistence of drug-induced cellular alterations after drug elimination has occurred, and the presence of drug in a "deep" effector site not detected by conventional pharmacokinetic analysis.[1] The formation of pharmacologically active metabolites is particularly relevant for the antiarrhythmic drugs, with their narrow therapeutic ratios, and is known to occur frequently.

From the Vanderbilt University School of Medicine, Nashville, Tennessee. This study was supported in part by Grants GM31304 and GM15431 from the United States Public Health Service. Dr. Roden is a recipient of the Clinical Scientist Award of the American Heart Association.

To individualize therapy and optimally monitor response, one must know the relative pharmacologic effects and potencies of a drug and its metabolites. During administration of the parent compound, the activity of metabolites can only be inferred, whereas direct comparisons of parent compounds and metabolites can be made in animal models. The final determination of pharmacologic activity of metabolites in man requires administration of the metabolites to patients. As outlined below, each of these approaches has been useful in the evaluation of antiarrhythmic drug metabolites.

Procainamide/N-Acetylprocainamide Studies

The rate of formation of N-acetylprocainamide, the major metabolite of procainamide, is influenced by a genetically determined pathway, N-acetylation. Because slow acetylators develop antinuclear antibodies and the lupus syndrome earlier in therapy than rapid acetylators,[2] this pathway can be viewed as relatively protective against lupus. Because antiarrhythmic activity was observed in patients with renal failure who accumulated much higher levels of N-acetylprocainamide than procainamide,[3] the hypothesis was advanced that N-acetylprocainamide might be an effective antiarrhythmic agent and that it might have the advantage of not inducing the lupus syndrome.[4] The next step in these studies was to compare the clinical pharmacologic properties of procainamide and N-acetylprocainamide in patients with ventricular arrhythmias.[5] N-acetyl-

FIGURE 2. Comparison of response to procainamide and N-acetylprocainamide. Reproduced from Roden et al[5] with permission of the publisher.

procainamide was found to be antiarrhythmic in a minority of patients, but frequently produced adverse effects that limited therapy. Plasma concentrations associated with antiarrhythmic efficacy and the occurrence of adverse effects are shown in Figure 1. Individual responses to procainamide after intravenous administration (before appreciable N-acetylprocainamide was produced) was compared with subsequent responses to a series of oral doses of N-acetylprocainamide. In keeping with their reported different electrophysiologic characteristics,[6] response to one agent was not predictive of response to the other (Fig. 2). Furthermore, in patients treated on a long-term basis with N-acetylprocainamide, antinuclear antibodies and the lupus syndrome did not occur.[5,7–9]

These data have been valuable in monitoring the contribution of N-acetylprocainamide to the pharmacologic effects seen during long-term procainamide therapy. Few patients, with the exception of those with renal dysfunction, have accumulation of N-acetylprocainamide to concentrations that might contribute to antiarrhythmic efficacy. On the other hand, toxic effects of N-acetylprocainamide may explain the occurrence of gastrointestinal adverse effects in some patients who receive procainamide. Most importantly, this series of studies illustrates the way in which the presence of an active drug metabolite may be deduced by indirect means after administration of the parent drug and its activity may be confirmed and characterized by giving the metabolite itself to patients.

Studies with Metabolism of Encainide

During the investigation of new antiarrhythmic drugs, elucidation of the relation between the concentration of drug in plasma and its pharmacologic actions can lead to early detection of active metabolites. This was well demonstrated during the evaluation of the antiarrhythmic, electrocardiographic and dose-response effects of the very potent procainamide analog encainide.[10] Patients with total abolition of ventricular ectopy and ventricular tachycardia had rapid encainide elimination (half-life of 2 to 4 hours), marked electrocardiographic effects at variable dosages (12.5 to 75 mg every 6 hours), and highly variable (but low, 1 to 60 ng/ml) plasma concentrations of encainide. In contrast, in early studies a single nonresponding patient had much slower encainide elimination (half-life of 7.8 hours), higher plasma encainide concentrations, and yet no antiarrhythmic or electrocardiographic effects at dosages up to 125 mg every 6 hours. Chromatographic analysis of plasma from the responding patients revealed that the O-demethyl metabolite of encainide was present in greater quantities than the parent drug (Fig. 3); yet in the nonresponder it was hardly detectable except at very high dosages of encainide. The highly variable relation between plasma encainide and effects and these pharmacokinetic data therefore strongly suggested O-demethyl encainide might be active. Subsequent studies in a larger number of patients revealed that 6 to 10% of patients appear to lack the ability to rapidly form O-demethylate encainide[11]; in this group, encainide accumulates to high plasma concentrations[12] (Fig. 4).

In the initial clinical studies,[10] the only patient who failed to respond to encainide therapy was also the only patient who failed to form significant quantities of O-demethyl encainide. While this observation was a major clue to the existence of this active metabolite, the conclusion that encainide itself was inactive has not been supported by further observations. First, rapid intravenous infusion of encainide produces plasma concentrations much higher than those seen during long-term administration of oral encainide (in the absence of any metabolites) and antiarrhythmic responses have been repeatedly documented in this setting.[12–14] Second, in the subset of the patients who are genetically incapable of rapidly forming O-demethyl encainide (estimated at 6 to 10% of the population[11]), encainide itself accumulates to these high plasma concentrations. In these patients, antiarrhythmic response has been reported during long-term oral encainide therapy at usual encainide doses (25 to 50 mg 3 or 4 times daily). Also, in a study comparing encainide and quinidine,[15] trough encainide plasma concentrations were <60 ng/ml in 17 of the 20 patients and concentrations of 200, 360 and 1,140 ng/ml were recorded at trough in 3. Therefore,

these subjects were probably metabolizing encainide poorly and lacked significant quantities of O-demethyl encainide in plasma. Two of the 3 patients were encainide responders, 1 at 25 mg every 6 hours and 1 at 50 mg every 6 hours; the third patient had 65% suppression of ventricular ectopic depolarizations. Therefore, poor metabolizers can respond to encainide and do so at usual dosages because they accumulate higher levels of the less potent parent compound.

The genetic variability in capacity to metabolize encainide has been used to evaluate the relative potency of encainide and its metabolites.[12] By administering an acute intravenous infusion of encainide to patients with ventricular arrhythmias, the pharmacologic effects of encainide could be determined before substantial quantities of metabolites could accumulate in plasma, especially in 2 patients with slow O-demethylation. An antiarrhythmic effect attributable to encainide itself was only seen when its plasma concentrations reached high levels (range 250 to 1,000 ng/ml). However, during long-term oral therapy in extensive O-demethylators, there was a good correlation between plasma O-demethyl encainide (usually 50 to 300 ng/ml) and effect.[12]

The pharmacologic properties of this metabolite have been directly evaluated in vitro[16] and in vivo[17,18] and it has been found to be 5- to 50-fold more active than the parent drug. Because its plasma concentrations usually exceed those of the parent encainide, it appears likely that it mediates most of the effects seen during encainide therapy in rapid O-demethylators. Some reported toxicity during encainide therapy may have been a result of rapid dose escalation, with the result that plasma concentrations of active metabolites (with apparently longer half-lives than encainide) accumulated into a toxic range.[19] Further evaluation of the pharmacologic properties of encainide metabolites in man awaits their direct administration to patients.

Studies with Quinidine and Metabolites

Metabolites of other antiarrhythmic agents may be active but few studies have shown direct and convincing evidence of pharmacologic effects in man. By comparing the effects of intravenous and oral quinidine in normal subjects, Holford et al[20] concluded that pharmacologically active metabolites caused a greater QTc prolongation after oral administration. This was the first convincing evidence that the metabolites of quinidine might be pharmacologically active in man, but the investigators could not assess the potential antiarrhythmic efficacy of the metabolites.

It has been asserted that the correlation between plasma quinidine concentration and antiarrhythmic

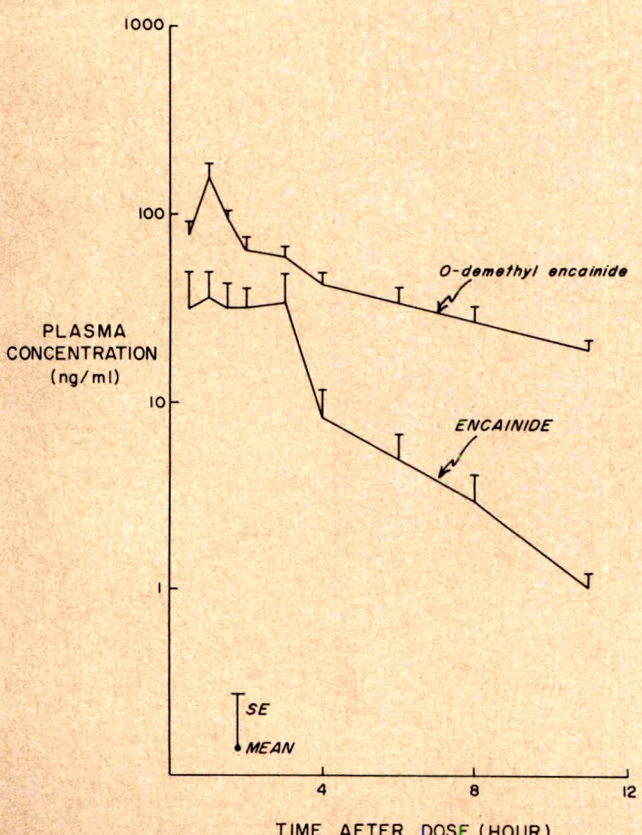

FIGURE 3. Plasma concentration of encainide and O-demethyl encainide after a 25-mg oral dose of encainide in patients who responded to encainide therapy. SE = standard error.

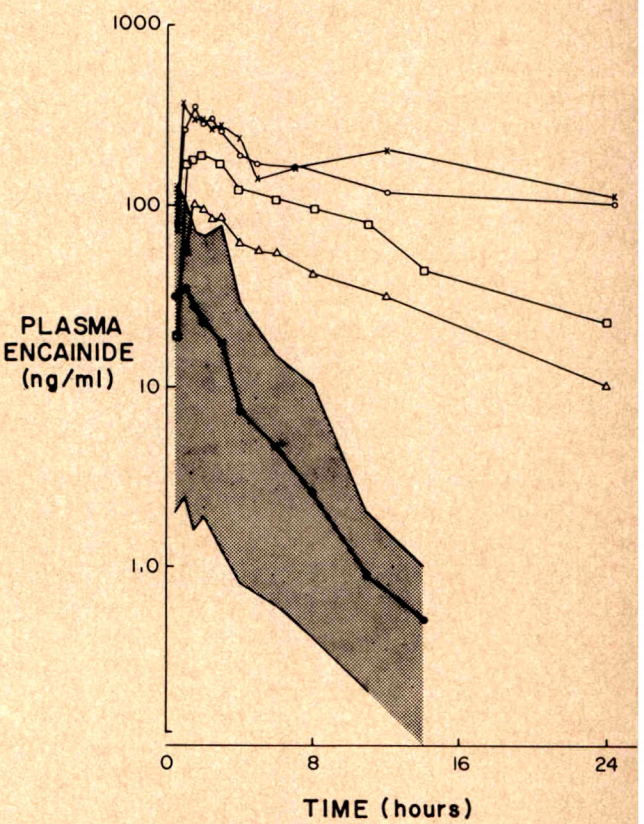

FIGURE 4. Plasma encainide concentration after a 25-mg oral dose of encainide. The upper 4 curves are from subjects with very slow elimination and no detectable O-demethyl encainide in plasma. O-demethyl encainide was seen in higher concentrations than encainide in the remaining subjects, whose mean data are shown by the **shaded area** (n = 15).

efficacy (conversion of atrial fibrillation) described by Sokolow and Edgar in 1950[21] was found only because the assay used was nonspecific and measured metabolites that contributed to pharmacologic activity.[22] Accordingly, the subsequently developed assays based on either double organic extraction,[23] enzyme immunoassay[24] or, more recently, high-performance liquid chromatography[25,26] are each more specific and therefore yield successively lower values when patient samples are assayed for "quinidine."[22,24] However, the relation between the more specific "plasma concentration" and antiarrhythmic efficacy has not been well defined. In addition to the indirect evidence in normal volunteers,[20] animal studies have been performed that suggest that some quinidine metabolites are active[27,28]; in one study, the major metabolite 3-hydroxy-quinidine actually exacerbated test arrhythmias.[28] As with procainamide and encainide, the rate of formation of this active quinidine metabolite appears to be highly variable.[29] Therefore, if the metabolites of quinidine do contribute to the effects seen in man, the newer assays may actually be less useful in monitoring therapy. Of equal importance, the newer assays (double organic extraction and enzyme immunoassay) might fail to measure metabolites that could accumulate to toxic concentrations.

Beta Blockers and Metabolites

Recent evidence has indicated the importance of active metabolites during beta-blocker therapy. Several metabolites of propranolol have been identified. One, 4-hydroxypropranolol, is formed principally after oral administration and appears to have beta-blocking properties.[30] Any interaction with propranolol itself is speculative. Another metabolite, the glucuronide, is itself not active but can be converted back to propranolol and may thus explain persistence of measurable propranolol plasma concentration days after stopping therapy.[31] Newer beta-blocking drugs (such as metoprolol and acebutolol) also have active metabolites; their contribution to the overall drug effect remains unknown. At least some of the variability in metoprolol metabolism is genetically determined, probably by the same gene that determines encainide metabolism.[32]

Metabolites of Other Antiarrhythmic Drugs

Lidocaine is de-ethylated in one pass through the liver to monoethylglycinexylidide and glycinexylidide. Using indirect techniques, it has been concluded that both have antiarrhythmic activity in man, but are less potent than the parent drug.[33,34] More importantly, monoethylglycinexylidide, like lidocaine, can produce seizures in animals, and addition of glycinexylidide to either appears to potentiate convulsant activity.[35] Unlike the parent drug, both metabolites are excreted in the urine. Monoethylglycinexylidide does not appear to accumulate in renal failure, probably because it is further de-ethylated to glycinexlidide. Although glycinexylidide may accumulate in renal failure, its overall contribution to the effects of lidocaine is probably small enough that no change in lidocaine dosing is required in renal disease. Lidocaine assay systems do not measure these metabolites.

Another antiarrhythmic agent, lorcainide, which has only recently been investigated in man, has a metabolite that appears to contribute significantly to antiarrhythmic and electrocardiographic effects during treatment.[36,37] In fact, the metabolite norlorcainide was administered to one patient and did suppress arrhythmias.[36] Disopyramide, verapamil and the investigational agents aprindine and amiodarone all have metabolites that may have antiarrhythmic activity. Mexiletine, tocainide and flecainide do not at this time appear to have active metabolites. However, the extent to which any metabolites accumulate in disease and the interactions between parent and metabolite have not been explored.[38] Should concentration monitoring in plasma become routine for these drugs, such data will be important.

Clinical Implications: Known and Potential

The presence of active metabolites of antiarrhythmic drugs can explain an unanticipated therapeutic effect such as arrhythmia suppression despite low plasma concentrations of procainamide in renal failure. An extremely variable relation between plasma drug concentration and effect should raise the possibility that active metabolites may be present (such as encainide). As outlined earlier, active metabolites of procainamide and perhaps many other drugs may also account for adverse effects during therapy. Also, some "idiosyncratic" adverse effects, such as agranulocytosis during aprindine therapy or quinidine-induced torsades de pointes, may be linked to genetically determined patterns of drug metabolism that are only now being explored. Further knowledge of the pharmacologic properties of active metabolites of antiarrhythmic drugs will help decrease the incidence of adverse effects and increase the frequency of successful therapy. Insights into the relation between structure and function in closely related compounds could allow the design of safer, more effective drugs.

Plasma Level Monitoring of Antiarrhythmic Drugs

ROBERT E. KATES, PhD

It is widely accepted that the effects (both cardiac and extracardiac) of antiarrhythmic drugs are modulated by their concentration at some unidentified active site, and that the drug concentrations in the systemic circulation and at these active sites are in equilibrium. Thus, antiarrhythmic drug effects can be related directly to systemic plasma concentrations, and an optimal plasma concentration can be identified at which satisfactory arrhythmia suppression can be achieved in the absence of intolerable adverse effects. This optimal concentration is influenced by several factors that give rise to significant interpatient variability. These factors include serum protein binding, active metabolites, intrinsic responsiveness and myocardial accumulation.

Although plasma concentration guidelines have been suggested for most antiarrhythmic drugs, they are generally not statistically derived and, with the exception of procainamide, are extrapolated from small patient samples. They generally represent the experience of an investigator or group of investigators treating a small homogeneous patient population. Interpretation of plasma concentrations of antiarrhythmic drugs also requires consideration of pharmacokinetic factors. Plasma drug levels are only useful when dosing history and timing of the blood sample, relative to drug administration, are considered.

Despite several limitations, plasma concentration monitoring of antiarrhythmic drugs can be helpful if evaluated with an understanding of the pharmacokinetic properties of the drug being measured, the clinical status of the patient and an appreciation of the factors that may influence the relation between the measured level and resultant clinical response.

(Am J Cardiol 1983;52:8C–13C)

Monitoring antiarryhythmic drug therapy by means of measuring blood or plasma concentrations dates back 40 years to the development of the first chemical method for measuring quinidine concentrations in human plasma.[1] After this report, several investigators evaluated the relation between the plasma concentration and cardiac effects of quinidine; in 1950, Sokolow and Edgar,[2] in an extensive report, described the clinical pharmacology of quinidine, and then proposed, for the first time, plasma concentration guidelines for an antiarrhythmic agent.

More than 20 drugs are either available for clinical use or are undergoing evaluation as antiarrhythmic agents. Analytic methods exist for measuring the plasma concentrations of most of these drugs, and an extensive literature has accumulated regarding their clinical pharmacology. Numerous studies that describe the disposition kinetics and the plasma level–effect relations of these drugs have been reported.

From the Division of Cardiology, Stanford University School of Medicine, Stanford, California.

It is now widely accepted that the effects (both cardiac and extracardiac) of antiarrhythmic drugs are modulated by their concentration at an unidentified active cellular site and that the concentrations in the systemic circulation and these active sites are in equilibrium. Thus, antiarrhythmic drug effects can be related directly to systemic plasma concentrations. Therefore, an optimal plasma concentration can be identified at which satisfactory arrhythmia suppression can be achieved in the absence of intolerable adverse effects. This optimal concentration is influenced by several factors, which gives rise to significant interpatient variability. The result of this variability is a range of therapeutic plasma concentrations. While these "therapeutic concentration ranges" are not always fully defined, they are useful because the plasma concentration-response relation is far more predictable than the relation between the dose and response.

The intent of this report is to summarize the state of knowledge that relates to the use of measured plasma levels of antiarrhythmic drugs and to discuss factors that modulate the relation between their measured plasma concentrations and cardiac effects.

TABLE I Degree of Serum Protein Binding of Antiarrhythmic Drugs

Drug	% Bound
Aprindine	90
Bretylium	6 ± 3.7*
Disopyramide	40–90†
Encainide	90
Lidocaine	25–50†
Lorcainide	85 ± 5*
Phenytoin	93.7 ± 0.4*
Procainamide	15–20
Propafenone	97
Quinidine	60–90
Tocainide	50
Verapamil	89.6 ± 0.17*

* Values are mean ± standard deviation.
† Concentration-dependent.

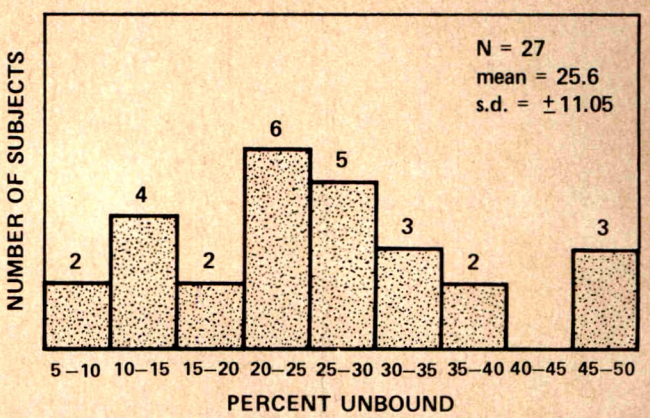

FIGURE 1. Degree of serum protein binding of quinidine in 27 patients. The total serum concentration in all samples was about 2 g/ml. Reproduced from: Kates RE. Therapeutic monitoring of antiarrhythmic drugs. Ther Drug Monit 1980;2:119–126, with permission of the publisher.

Factors That Influence the Plasma Level–Effect Relation

Protein binding: Much has been written about the role of plasma protein binding of drugs and the role it plays in moderating the plasma level–effect relationship.[3,4] The accepted view is that only free drug molecules (not bound to plasma proteins) in the plasma equilibrate with drug at the active site in the myocardium because only free drug molecules can cross cell membranes. Thus, only unbound drug is available to produce an antiarrhythmic effect. All antiarrhythmic drugs bind to plasma proteins, and several are highly bound (Table I). In most cases this binding is relatively constant from patient to patient, but for a few drugs there is considerable interpatient variability. Also, the extent of binding of most drugs is independent of the total plasma concentration. Lidocaine and disopyramide are exceptions to this rule in that their binding decreases with increasing total plasma levels due to saturation of the protein binding sites. Some of the variability in response to antiarrhythmic drugs may be due to differences in the extent of plasma protein binding. For highly bound drugs, small changes in the extent of binding can make significant differences in the effective free concentration and, possibly, activity.

In almost all cases the actual measured plasma concentrations of antiarrhythmic drugs represent total (bound plus free) drug in the plasma. The evaluation of the degree of protein binding can be determined by means of equilibrium dialysis, ultrafiltration or ultracentrifugation. Although these are viable procedures in a research environment, they are too time-consuming and costly to be performed as a routine clinical laboratory procedure. Although one does not usually have binding data available for an individual patient, it is necessary to keep in mind that variability in binding translates into variability in free concentration, which affects the relation between the total plasma concentration and the effect. An example of interpatient variability is shown in Figure 1, which is a summary of quinidine protein binding data from 27 patients. The total measured plasma concentration of quinidine in each patient sample was approximately 2 μg/ml, and there was no significant difference in the total serum protein or albumin concentration in these samples. These data show that the interpatient variability in quinidine binding is substantial, with a range of 5 to 50% for unbound drug. The actual free plasma concentration of quinidine varied from 0.1 μg/ml in patients with only 5% free to 1 μg/ml in those with 50% free. The free concentrations varied by a factor of 10, even though all patients had the same measured total plasma concentration of quinidine. In considering protein binding data, such as presented in Table I, the magnitude of the range is at least as important as the average value. When a patient has signs of toxicity or is nonresponsive to an antiarrhythmic drug despite measured total plasma levels within the generally accepted therapeutic range, a factor that should be considered is the plasma protein binding.

In addition to interpatient variability in plasma protein binding, intrapatient variability can contribute to the difficulty of interpreting total plasma drug concentrations. Intrapatient variability can be due to physiologic changes, drug interactions, concentration-dependent saturable binding, or physiologic variation in the disease process. Routledge et al[5] reported changes in lidocaine binding in patients after acute myocardial infarction. After an infarction, plasma concentrations of alpha$_1$-acid glycoprotein, a protein to which lidocaine binds, increase with time. The protein binding of lidocaine increases, with a subsequent reduction in free fraction. Their study demonstrated a statistically significant change in lidocaine binding with time in post-infarction patients; however, the clinical significance remains to be further documented.

Concentration-dependent binding has been reported for 2 antiarrhythmic drugs—disopyramide and lidocaine. This phenomenon not only confuses the interpretation of measured drug concentrations, but greatly increases the complexity of titrating patients to an optimal dose. The concentration-dependence of the plasma protein binding of disopyramide in 2 patients reported by Meffin et al[6] is shown in Figure 2. The free fraction increases dramatically for both patients over

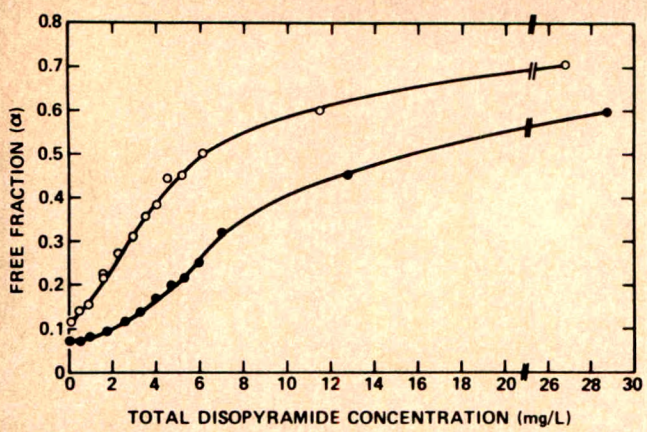

FIGURE 2. Free fraction of disopyramide in the plasma versus the total plasma concentration. Patients 11 (**open circles**) and 12 (**solid circles**) from Meffin et al.[6] Reproduced from Meffin et al[6] with permission of the publisher.

TABLE II Metabolites of Antiarrhythmic Drugs

Drug	Major Metabolites	Relative Potency	Relative Plasma Concentration
Amiodarone	N-desethylamiodarone	...	1
Aprindine	N-desethylaprindine	1	0.2
Disopyramide	N-desisopropyl-diso-pyramide	<0.5	0.5
Encainide	O-demethylencainide	>1	5
	3-methoxy-O-demethyl-encainide	≥1	5
Lidocaine	Monoethylglycine xylidide	0.83	0.5–2
	Glycine xylidide	0.1	0.1–1
Lorcainide	Norlorcainide	1	0.5–4
Procainamide	N-acetylprocainamide	<1	0.5–2.5
Quinidine	3-hydroxyquinidine	1	0.2–0.8
Verapamil	Norverapamil	0.25*	1

* The potency of norverapamil relates to its vasodilatory properties; its effects on cardiac conduction have not been reported.

the range of generally observed therapeutic levels (3 to 6 μg/ml). As the total plasma concentration of disopyramide increases from 1 to 6 μg/ml in Patient 11, the free fraction increases from 0.175 to 0.49. The consequence of an increase in total disopyramide concentration from 2 to 4 μg/ml is an increase in the actual free concentration by a factor of 4. Thus, small changes in the total plasma concentration can produce significantly larger changes in the actual free (active) concentration. Subsequently, a much greater response than anticipated based on the total plasma level might occur. Such a situation suggests a need for caution when titrating a drug with nonlinear binding. Similar data have been reported for lidocaine.[7] As the total plasma concentration of lidocaine is increased through the therapeutic range from 1 to 6 μg/ml, the free concentration increases from about 25 to 50% of the total. Since lidocaine is not highly bound in the plasma, this change in extent of binding does not represent as significant a concern as with disopyramide.

Active metabolites: Most antiarrhythmic drugs are extensively metabolized.[8] In some cases, the metabolites produced are cardioactive and accumulate extensively. Active metabolites of some antiarrhythmic drugs may be of equal or greater potency than their parent drug, or may even produce effects that are qualitatively different. In some cases, metabolites may produce noncardiac adverse effects that limit the clinical value of the parent drug. Listed in Table II are the major metabolites of several antiarrhythmic drugs. These metabolites either have been reported to accumulate in plasma of patients after administration of the parent drug or have been reported to be pharmacologically active. Some of these metabolites meet both criteria, are cardioactive and accumulate extensively. Evaluations of activity of antiarrhythmic drug metabolites are generally conducted in animal arrhythmia models, and only rarely have metabolites been studied after direct administration to patients. However, from knowledge of antiarrhythmic activity in animals and of the degree to which a metabolite accumulates in the plasma of patients, qualitative judgments can be made about its therapeutic role. Such judgments, however, must be recognized as tenuous. Quantitative judgments require further information regarding the relation between the parent drug and the metabolites when present simultaneously in the myocardium. One must consider whether the effects of the parent drug and metabolite are additive, synergistic or even antagonistic. The latter case is most likely with drug-metabolite pairs in which the metabolite accumulates substantially but does not have significant antiarrhythmic potency.

The role of metabolites also must be considered with regard to differences in the disposition kinetics between a parent drug and metabolite. As has been demonstrated by the metabolites of lorcainide[9] and encainide,[10] the time course of accumulation and disappearance of a metabolite may be much different from that of the parent drug. Norlorcainide and the active metabolites of encainide have much longer half-lives and smaller distribution volumes than their parent drugs. While steady-state plasma levels of encainide and lorcainide are achieved rapidly, it requires several days to weeks before their metabolites have accumulated to their steady-state levels. Figure 3 illustrates the difference in disposition characteristics of encainide and its 2 active metabolites. These data were obtained during a washout phase of a long-term oral dosing study.[10] The disappearance half-lives of the 2 metabolites are considerably longer than that of the parent drug. Clinical assessment, as well as interpretation of a measured plasma concentration, must take into account the time required to achieve steady-state concentrations of the relevant metabolites as well.

The n-acetyl metabolite of procainamide (NAPA) has received considerable attention over the past years,[11,12] and much confusion has arisen regarding the interpretation of simultaneously measured procainamide and NAPA levels. Procainamide and NAPA are qualitatively and quantitatively different in their effects on cardiac conduction.[13,14] Unless NAPA accumulates to plasma levels greater than about 15 μg/ml in patients who are taking procainamide, its accumulation is of

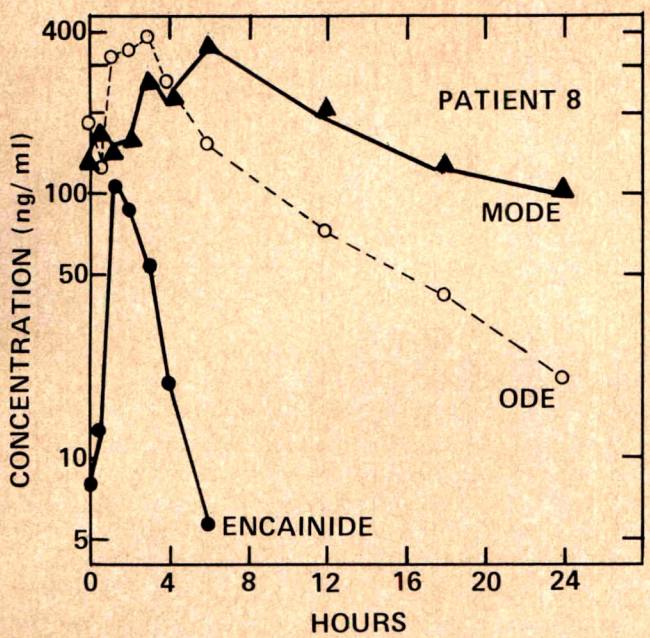

FIGURE 3. Plasma concentration-time curves for encainide (**closed circles**), O-demethyl encainide (ODE) (**solid circles**) and 3-methoxy-O-demethyl encainide (MODE) (**triangles**) in a patient after discontinuation of long-term oral encainide therapy. Reproduced from Kates et al[10] with permission of the publisher.

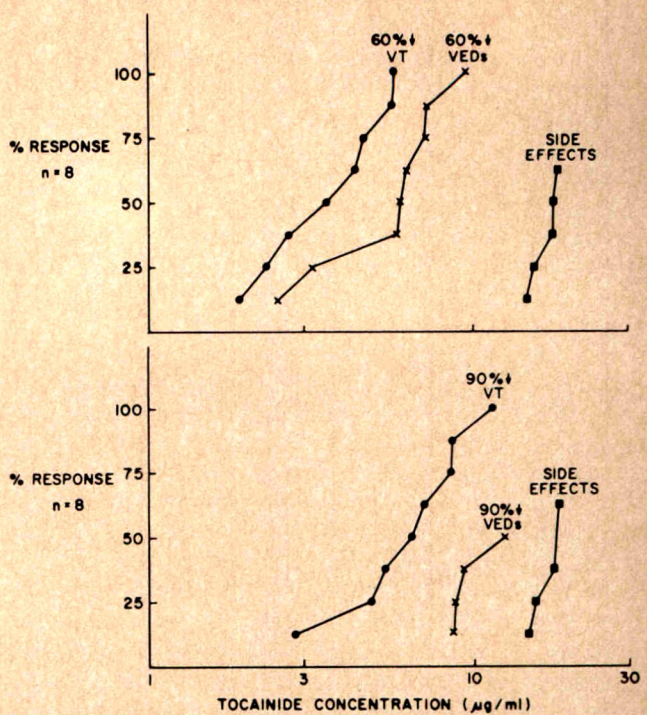

FIGURE 4. Dose-response relationships for suppression of ventricular ectopic depolarizations (VED), ventricular tachycardia (VT) and side effects for 8 patients with frequent VT. Reproduced from Roden et al[16] with permission of the publisher.

little consequence. However, the accumulation of NAPA to levels >15 μg/ml due to renal failure or other causes confounds the interpretation of measured procainamide plasma levels. As with other parent drug–metabolite combinations, no good guidelines exist for evaluating their combined effect, and caution must be exercised.

Most analytic methods used in clinical drug assay facilities measure only the unchanged parent drug. The presence of >1 active species (parent drug plus metabolites) clearly confounds the interpretation of a measured drug level.

Intrinsic responsiveness: In addition to the concentration of drug at some active site in the myocardium, the clinical effectiveness of an antiarrhythmic drug also depends on the responsiveness of this target tissue. Factors that influence responsiveness include type of arrhythmia, other concurrent physiologic abnormalities, environmental factors, genetic influences and, in some cases, previous drug therapy.

Connolly et al[15] reported that repetitive ventricular activity is suppressed at plasma drug concentrations lower than those required to suppress isolated ventricular premature beats. Roden et al[16] evaluated the clinical efficacy of tocainide in patients with symptomatic ventricular arrhythmias and related arrhythmia suppression to plasma tocainide levels. They found that tocainide suppressed ventricular tachycardia to a greater extent than isolated ventricular ectopy at all concentrations and that increases in plasma levels produced progressive suppression of both. Their data demonstrated parallel, but distinctly different, plasma level–response relations for repetitive and single forms of ventricular ectopy (Fig. 4).

We recently observed similar differential effects with propafenone.[15] The relation between arrhythmia suppression and plasma levels of propafenone was studied in patients with histories of frequent ventricular premature contractions. Repetitive ventricular activity was suppressed at plasma concentrations lower than those required to suppress isolated extra beats.

Although the plasma level–effect relation for single and repetitive forms of ventricular ectopy are different, they do overlap the same concentration range, and the differences are probably not clinically important. These observations do, however, suggest that different mechanisms may be responsible for single and repetitive forms of ventricular ectopy. These differences in plasma levels associated with suppression of isolated and repetitive ventricular ectopy suggest the need to consider the arrhythmia being suppressed when "therapeutic levels" are being defined. Furthermore, it is clear that the relation between plasma drug levels and the prevention of ventricular fibrillation is unknown.

In addition to arrhythmia sensitivity, other physiologic factors have been shown to influence responsiveness to drug therapy. As pointed out by Koch-Weser,[17] hypokalemia, hypercalcemia, hypomagnesemia, acid-base disturbances, increased adrenergic tone, hypothyroidism, hypoxemia, myocardial ischemia and severe cardiac failure all can influence the response to digoxin therapy.

Myocardial uptake: The cellular site of action of antiarrhythmic drugs is not known. However, it has

been assumed for years that a receptor, or membrane binding site, is involved in the action of drugs that affect cardiac conduction. The argument that free (non–protein-bound) drug in the plasma is a good measure of the concentration of "active" drug at the receptor site rests on the hypothesis that a reversible interaction occurs between free drug and a binding site, as described by classic enzyme kinetics. It has been argued that myocardial binding of antiarrhythmic drugs is primarily to inactive sites[17] and that free plasma levels better reflect the "active" drug concentration in the myocardium. This generally accepted assumption, however, deserves closer evaluation.

Anderson et al[18] have studied the time course of action of bretylium in a dog model, and reported that the time course of action of this drug correlates better with the time course of uptake and disposition of drug in the myocardium than with plasma concentrations. After a single intravenous bolus dose of bretylium, the maximal effect was not observed until 6 hours after administration, despite the significant decrease in plasma concentrations over this time period. They observed, however, that myocardial tissue levels of this drug increased over this time period, reaching a maximal level around 6 hours. They attributed this slow onset of action to the delay in myocardial uptake. A similar finding was reported for amiodarone.[19] The delay in uptake of amiodarone into the myocardium of anesthetized dogs also was shown to correspond with the delay in onset of effect. These 2 drugs demonstrate that myocardial tissue levels may be important determinants in modulating the effect of antiarrhythmic drugs. These 2 drugs are unique in that they are taken up slowly into the myocardium, and, at early times, plasma and myocardial levels are not changing in parallel. This allows a separate look at the relation between the plasma and the myocardial drug concentrations and effects.

Other studies in dogs have shown that considerable variability can exist in the myocardial/plasma concentration ratio[20,21] of antiarrhythmic drugs. Where myocardial tissue levels of antiarrhythmic drugs moderate their effects, this variability in myocardial/plasma concentration ratios may significantly contribute to variability in effective plasma concentrations.

When Is It Helpful to Measure Plasma Concentrations of Antiarrhythmic Drugs?

Numerous factors can influence the relation between the plasma concentration and the effect of antiarrhythmic drugs. Despite these concerns, plasma level monitoring of antiarrhythmic drugs can be useful. Plasma concentrations of antiarrhythmic drugs are especially helpful in guiding dosage adjustments when therapeutic endpoints are not readily measurable. The most obvious situation is prophylactic therapy to prevent recurrences of paroxysmal arrhythmias, including sudden death. In this situation, one has the option to adjust a dosage regimen to toxicity and then back off, or to adjust the dose to achieve plasma concentrations within established guidelines. The former is a viable approach in some environments in which close patient monitoring is possible, and early toxicity is neither life-threatening nor intolerably severe. However, the use of plasma level monitoring to adjust dosage is generally safer, simple and inexpensive. Plasma level guidelines, as used in this situation, are imperfect but do provide a reasonable basis for dosage adjustment in the absence of other quantifiable endpoints.

Another important use of plasma level monitoring of antiarrhythmic drugs is in the evaluation of therapeutic failures. Failure to suppress symptomatic or otherwise detectable arrhythmias with reasonable or high drug doses can be due to "true therapeutic failure," to bioavailability or pharmacokinetic factors or to poor patient compliance. As mentioned earlier in this report, the relation between administered dose and effect is far less predictable than the plasma level–effect relation. A major factor that influences the dose-response relation is bioavailability. Due either to poor absorption or high hepatic extraction, an administered dose may not reach the systemic circulation in sufficient amounts to produce effective concentrations at the active site. The only way to differentiate this problem from a true therapeutic failure is to evaluate the drug concentration in the blood. Bioavailability deficiencies can be overcome by dosage adjustments, whereas true therapeutic failures require changing to another drug.

Plasma concentration monitoring of antiarrhythmic drugs is also useful when their absorption or disposition is altered by pathophysiologic changes. Benowitz and Meister[22] reviewed the effects of cardiac failure on the pharmacokinetic properties of several drugs. They pointed out that cardiac failure is frequently associated with alterations in cardiac output, autonomic tone, central and systemic venous pressure, tissue hypoxia, visceral congestion and gastrointestinal motility. Cardiac failure significantly alters the dispostion kinetics of both quinidine[23] and lidocaine.[24] In both cases the clearance is reduced and the distribution volumes are less than normal. The consequence of these changes is higher plasma levels for a given dosage regimen. Although the direction of this alteration is predictable, considerable variability exists in the degree of these changes. Thus, monitoring plasma levels is extremely helpful.

Other situations in which plasma level monitoring of antiarrhythmic drugs is useful are emergency admissions, treatment of patients with impaired renal or hepatic function, and those in which concurrent administration of interacting drugs is necessary.

Pharmacokinetic Factors

Plasma drug levels can be interpreted only when dosing history and timing of the sample, relative to a prior dose, are considered. During long-term oral drug administration, it is generally recommended that blood be drawn near the end of the dosage interval so that the measured concentration represents the minimal or trough level. Within a dosage interval, levels can change dramatically, especially for rapidly eliminated drugs. At the very least, it is necessary to document the time a blood sample was drawn relative to the prior dose.

TABLE III Plasma Level Guidelines for Antiarrhythmic Drugs

Drug	Plasma Level Range (μg/ml)
Amiodarone	0.5–2
Aprindine	1–2
Bretylium	0.8–2.4
Disopyramide	3–6
Lidocaine	1.4–6
Lorcainide/norlorcainide	0.04–0.2/0.08–0.3
Mexiletine	0.75–2
Phenytoin	10–18
Procainamide	4–8
Quinidine	2–5
Tocainide	6–15

It is also important to consider how long a patient has been taking a particular drug and whether there has been any recent change in the dosage regimen. Although the interpretation of a measured plasma concentration does not necessitate that a steady state be achieved before drawing a blood sample, it is useful to know if a steady state has been achieved or if further accumulation can be anticipated with the current regimen. A time period equivalent to about 5 times the half-life of a drug is necessary to achieve steady-state. This principle applies whether one is initiating therapy with a new drug or simply changing the dose or dosing frequency. As stated earlier, metabolites may have longer half-lives than their parent drug. Their time of accumulation also must be considered, especially if they are cardioactive.

Therapeutic Ranges

The concept of a therapeutic range is best illustrated by the report of Koch-Weser and Klein[25] in which they relate clinical status to plasma concentrations of procainamide for 146 patients who were treated for cardiac arrhythmias. Their data demonstrated a normal distribution of plasma concentrations associated with clinical efficacy. They identified a lower level, below which the probability of a therapeutic response was low, and an upper limit, above which the probability of toxicity was significant. Although they demonstrated a broad range of plasma levels over which arrhythmia suppression was achieved, most patients responded within the range of 4 to 8 μg/ml. "Therapeutic plasma concentration ranges" have been suggested for most antiarrhythmic drugs (Table III). The title "therapeutic range" is a misnomer and probably generates greater expections than are justified. A more appropriate title would be "plasma level guidelines." Whereas the therapeutic range for procainamide is based on a large patient sample, with a sufficient occurrence of level-related toxic side effects, this is not the case for most other antiarrhythmic drugs. These ranges are not statistically derived and, with the exception of procainamide, are obtained from small patient samples. They generally represent the experience of an investigator or group of investigators treating a small homogeneous patient population. These ranges are not rigorous and, in most cases, must be extensively refined by the evaluation of larger numbers of patients. The plasma levels associated with increasing likelihood of level-related toxicity need to be defined more carefully for almost all antiarrhythmic drugs.

Conclusions

Plasma concentration guidelines have been proposed for most antiarrhythmic drugs. The relation between measured plasma concentration and effect is not well characterized for most drugs, and it is recognized that it is influenced by several variables. Despite several limitations, plasma concentration monitoring of antiarrhythmic drugs can be helpful if evaluated with an understanding of the pharmacokinetic properties of the drug being measured and the clinical status of the patient being treated.

Hemodynamic Effects of Antiarrhythmic Drugs

PAUL J. BLOCK, MD, and ROGER A. WINKLE, MD

In order to use antiarrhythmic drugs safely, one must understand their hemodynamic effects. Quinidine and the calcium antagonists have direct cardiac effects and frequently opposing autonomically mediated or indirect cardiac effects. Lidocaine is exceptionally well tolerated, even by patients with severe left ventricular dysfunction. Phenytoin and procainamide have the potential for serious adverse effects, but are generally well tolerated at usual doses. Disopyramide causes serious depression of left ventricular function in many patients because of its direct myocardial depressant and peripheral vasoconstricting actions. Although bretylium causes an immediate increase in contractility, it can ultimately result in important hypotension. In this review the in vitro and in vivo hemodynamic effects of these and other antiarrhythmic drugs are discussed to provide information that will assist the clinician in using these drugs properly.

(Am J Cardiol 1983;52:14C–23C)

Patients with coronary artery disease, cardiomyopathy or significant valvular heart disease often have symptomatic or life-threatening arrhythmias that require short- or long-term drug therapy. In these patients, many of whom have a marginally compensated cardiovascular system, one must be concerned about a drug's cardiac and peripheral vascular effects. A small further decrease in myocardial contractility or a change in peripheral vascular resistance may mean the difference between compensated congestive heart failure and pulmonary edema or the difference between borderline low blood pressure and symptomatic hypotension or shock. It is important to understand all of the cardiovascular effects of any antiarrhythmic medication in order to choose the most appropriate agent for any clinical setting.

For these reasons, we review the hemodynamic effects of the frequently used antiarrhythmic agents. Although for many drugs discussed we describe the findings of relevant in vitro and in vivo animal experiments, the major emphasis is on studies that are most applicable to the care of the patients with heart disease. We focus on the drugs that are often prescribed, with less emphasis on medications that are still under investigation and are not yet available for widespread use.

A review of the hemodynamic effects of antiarrhythmic drugs shows a variety of contradictory results. A drug that has a negative inotropic effect in one setting will be shown to increase cardiac output in another. Frequently, the methods used for evaluation can explain these differences. Distinguishing the primary from the secondary effects of an antiarrhythmic drug is important because many of the drugs have a direct effect on the myocardium that is offset by a peripheral or adrenergic effect (Table I). Similarly, direct effects of an agent may be balanced by autonomic reflex actions in response to those or other direct actions. Depending on the balance, overall effects can vary greatly. These interactions can often explain the differing results of studies of isolated myocardial tissue versus those of studies of an intact organism. They can also explain differences between animals with their autonomic reflexes altered, either pharmacologically or surgically, and those that have not been so treated. Other, more obvious factors explaining these differences relate to variation in dose and rate of administration of a drug, nonuniform effects from species to species, and the difficulty in extrapolating these to man, and the differences between anesthetized and unanesthetized subjects. Finally, a distinction must be made between statistically significant and clinically significant results. Some minor hemodynamic effects of an antiarrhythmic drug detected by sensitive methods may reach statistical significance, but have little clinical relevance.

From the Cardiology Division, Stanford University Medical Center, Stanford, California.

Quinidine

Recognizing the primary and secondary cardiovascular effects of quinidine is difficult. Some studies of isolated cardiac muscle have shown quinidine to reduce contractile force;[1–3] others have shown a slight increase in contractility,[4] and one showed a positive or negative effect, depending on the quinidine concentration and the rate of electrical stimulation.[5] Overall, depression

of contractility appears to be related to the quinidine concentration. Only minor negative inotropic effects were seen at clinically relevant plasma levels, with significant depression of contractility noted only at considerably higher levels.[1–3]

Most in vivo studies have revealed both direct myocardial and peripheral vascular effects that are important in the overall hemodynamic response to intravenous quinidine. In almost all intact animal models, intravenous quinidine produces significant peripheral vasodilation.[6–15] Schmid et al[14] demonstrated that the peripheral vasodilating effect is produced by 2 independent mechanisms. One is by a direct action to relax vascular smooth muscle and the other is by alpha-adrenergic blockade producing inhibition of adrenergic constrictor tone.[15]

These findings explain the significant decrease in blood pressure and systemic vascular resistance seen after the administration of intravenous quinidine in laboratory animals.[6–15] An animal study of the hemodynamic effects of oral quinidine[16] did not reveal any effect on blood pressure after 10 days to 2 weeks of therapy.

Conclusions from studies evaluating quinidine's effects on myocardial contractility are considerably more variable and the mechanisms more complex. Most animal studies evaluating myocardial contractility with the use of a myocardial strain gauge, by measurement of peak first derivative of left ventricular (LV) pressure (dP/dt) or by measurement of cardiac output, have found that intravenous quinidine depresses myocardial contractility transiently.[7,11,12,17] However, others have shown no significant change[9,10] or an increase[8,13] and some have yielded variable results from subject to subject.[6]

Several important studies help to clarify these apparently contradictory results. Folle and Aviado[6] reported a variable effect on myocardial contractility from animal to animal and had 3 dogs in which an increase in contractility was abolished by adrenalectomy. In 2 other studies,[8] intravenous quinidine alone produced an increase in myocardial contractility compared with control values. However, after propranolol, intravenous quinidine produced either a decrease[8] or no change[13] in contractility. These investigations support the concept that quinidine has no direct positive inotropic effect, but produces reflex sympathetic stimulation secondary to the hypotension it induces. Unfortunately, not all studies have shown these results. A study by Stern[11] showed a combination of propranolol and quinidine to produce less depression of myocardial contractility than either drug given alone. O'Rourke et al[16] found no change in myocardial contractility in dogs treated for 2 weeks with oral quinidine.

Few hemodynamic studies of quinidine have been performed in man. One study of 5 heart transplant recipients[18] evaluated the effects of intravenous quinidine. The study revealed a significant decrease in blood pressure and cardiac output and, using an assumed right atrial pressure, no change in systemic vascular resistance. Intravenous quinidine decreased both end-systolic and end-diastolic volumes without any change in ejection fraction. The investigators interpreted their results as demonstrating a possible effect of quinidine to increase venous capacitance, leading to decreased preload with the expected hemodynamic results. The lack of any effect of quinidine on systemic vascular resistance in that study is not well explained.

Several studies of the effects of oral quinidine have been performed both in normal volunteers[19–21] and in patients with heart disease.[20–22] Overall, oral quinidine in standard antiarrhythmic doses has few clinically important hemodynamic effects as assessed by noninvasive methods. One early study[21] used a single 800-mg

oral dose of quinidine and showed a significant decrease in blood pressure with a concomitant decrease in systemic vascular resistance in many patients. Patients with a poor cardiac output at rest had an improved cardiac output, whereas those with normal cardiac output at rest had a decrease. This may again be due to an effect on capacitance and resistance vessels to produce both a decrease in preload and afterload with its consequent hemodynamic effects.

Overall, oral quinidine in standard doses appears to be well tolerated, without significant adverse hemodynamic effects, even in patients with LV dysfunction. This conclusion is supported by results of the Boston Collaborative Study,[23] in which 652 patients taking quinidine had no exacerbation of congestive heart failure despite a predrug incidence of 35%. The primary hemodynamic effect of intravenous quinidine is peripheral vasodilation of both capacitance and resistance vessels. Its effect on cardiac output will depend on the balance between changes in preload and afterload and the patient's preexisting hemodynamic state. There is usually a significant decrease in systemic blood pressure, which can often be avoided by rapid volume expansion during the quinidine infusion. Although quinidine does exert a mild negative inotropic effect, this may be offset by a reflex increase in sympathetic tone and is of less clinical importance than the drug's peripheral effects.

Procainamide

Studies of the hemodynamic effects of procainamide have also yielded conflicting results. An in vitro study of its effect on an isolated papillary muscle preparation showed no negative inotropic effect at concentrations equivalent to clinically effective plasma levels and an increase in contractility at higher concentrations.[1] This has not been observed in studies on intact animals.

Most in vivo animal studies demonstrate a negative inotropic effect after large doses of intravenous procainamide.[6–8,24,25] Most also show a significant decrease in systemic blood pressure,[6–8,24–26] without a significant decrease in systemic vascular resistance.[8,25] At similar doses, however, some studies have shown no significant hemodynamic effects of intravenous procainamide[27] and others have shown a negative inotropic effect only at high doses, with a positive inotropic effect observed at lower doses.[26] Despite the lack of effect on systemic vascular resistance in these studies, the ability of procainamide to produce vasodilation is well known.[6,28] Why its peripheral effects were not clearly seen in all studies is not known.

The hemodynamic effects of intravenous procainamide in man have been studied extensively.[29–37] The effects seen relate not only to the total dose administered but to the rate of administration.[31] Several studies have shown that the drug has a negative inotropic effect at therapeutic doses.[29,33,34,37] One study[29] of intravenous procainamide in patients undergoing cardiac surgery showed decreases in contractility (measured by the use of a strain gauge sutured to the right ventricle) at doses of 2 and 4 mg/kg. Most other studies have also found that the myocardial depression is dose-related.[29,34] Only occasional studies have demonstrated a decrease in cardiac output,[33,34] and these changes have generally been small and not of clinical significance. Although this degree of decrease in contractility is of minor importance at the doses generally used, the possibility of more serious clinical effects at higher doses does exist.

Most studies in man have shown a significant decrease in systemic blood pressure after the administration of intravenous procainamide,[29,33–36] but others have shown little, if any, effect.[30–32] The difference may again relate to the total dose and the rate of administration. The decrease in blood pressure is thought to be related to peripheral vasodilation, but no consistent change in systemic vascular resistance has been observed.[33,34]

Overall, at usual antiarrhythmic doses, procainamide has a mild-to-moderate negative inotropic effect and produces a transient decrease in systemic blood pressure. The effects appear related to both total dose and rate of administration. In general, it is well tolerated even in patients with LV dysfunction or acute myocardial infarction.[25,31,32] However, the possibility of clinically important effects at high doses in patients with severe LV dysfunction exists, and procainamide should be used with caution under these circumstances.

Lidocaine

One in vitro study assessing the effect of lidocaine on the isometric contractile force of isolated cardiac muscle had demonstrated a negative inotropic effect[1] and another found little or no depressant effect.[3] The concentration of lidocaine used varied between these 2 studies, and decreased contractility was seen only with concentrations greater than those used clinically.[1]

Hemodynamic evaluations in intact animals have shown similar results. Assessment of LV function after administration of intravenous lidocaine by the measurement of changes in peak dP/dt,[12,24,25,38] by the use of a myocardial strain gauge,[12,26] or by the construction of ventricular function curves[24] have all demonstrated similar effects. Lidocaine in doses frequently used in clinical practice has little, if any, hemodynamic effect. The changes observed have consisted of very small transient and clinically insignificant decreases in LV contractile force,[26] LV peak dP/dt[38] and systemic blood pressure.[26,39] These minor changes all returned to control values by 5 to 10 minutes after a bolus was administered.

These investigations all show that at very high doses (4 to 40 mg/kg), lidocaine demonstrates dose-related myocardial depression.[12,24–26,38] Statistically and clinically important decreases in contractile force,[12,26] LV peak dP/dt,[12,24,25,38] cardiac output[25] and systemic blood pressure[12,24–26,39] were consistently seen at doses that would be toxic in man.

Many clinical studies have evaluated the hemodynamic effects of lidocaine.[29,31,32,40–44] The population used for each investigation was different, but in several studies lidocaine was administered to patients undergoing hemodynamic monitoring during an acute myocardial infarction[31,32,40,43] or to patients with coronary

artery disease or significant LV dysfunction.[31,41,42] Even in this group of patients, in which one would expect to see the most dramatic results of any adverse hemodynamic effects, no clinically significant changes in myocardial function or systemic blood pressure were observed.

These data support the long-standing clinical experience that standard doses of intravenous lidocaine can be used safely without untoward hemodynamic effects, even in patients with acute myocardial infarction and severe LV dysfunction. Although sensitive measurements can detect a mild myocardial depressant effect, this rarely is of clinical significance at the doses generally used. The experimental studies do demonstrate that at very high levels, lidocaine can exert significant negative inotropic effects.

Bretylium

Bretylium is unique among the antiarrhythmic agents in that short-term studies on isolated cardiac muscle,[1,45–48] in intact animals[49,50] and in man[51] have all shown that it possesses a positive inotropic effect on cardiac muscle.

In vitro studies on isolated papillary muscle preparations have shown that bretylium concentrations similar to those used in clinical medicine have a dose-related positive effect on contractile force.[1,45–48] Pretreatment of animals with reserpine to produce catecholamine depletion or the addition of propranolol to the bath prevent this positive inotropic effect,[45,46] suggesting that bretylium's positive inotropic effect is not a direct effect but rather the result of myocardial catecholamine release. Other studies have shown both a direct and an indirect effect leading to increased contractility.[48] There is little question, however, that myocardial catecholamine release plays a major role. It may be that at lower doses, this effect is primary and that at higher doses a direct positive inotropic effect occurs.[52]

Several in vivo animal investigations support the conclusions from the in vitro studies.[49,50] A canine study by Gilmore and Siegel[50] demonstrated an immediate decrease in LV end-diastolic pressure after the administration of bretylium at a time when heart rate and cardiac output were constant, a finding interpreted as consistent with an increase in contractility. During this period, coronary venous blood samples showed a consistent increase in catecholamine content, followed by an increase in arterial catecholamine concentration. After the injection of bretylium, stimulation of cardiac sympathetic efferent nerves produced little cardiac response and little or no increase in myocardial catecholamine release compared with pre-bretylium values. This effect was not simply due to catecholamine depletion, because tyramine caused an adequate catecholamine release. The mechanism of this blocking action is unknown.

The early positive inotropic effect of bretylium was demonstrated in man by Jorgensen et al,[51] who showed that an intravenous infusion produced an immediate increase in cardiac index, arotic pressure and LV peak dP/dt. However, 30 minutes after the infusion, the aortic pressure and cardiac index had returned almost to control values and the peak dP/dt was past its maximum and beginning to decrease. The prior administration of propranolol blocked most of these effects, again suggesting the role of catecholamine release.

In a subsequent investigation by Chatterjee et al,[45] bretylium was given to patients within 72 hours of an acute myocardial infarction and hemodynamic variables were studied for 2 hours. There was an early increase in blood pressure and heart rate accompanied by an increase in systemic vascular resistance. However, no change in cardiac index or intracardiac pressures was observed. Two hours after the infusion, blood pressure, systemic vascular resistance and heart rate were all below control values, still with no significant change in cardiac index or filling pressures.

Bretylium's most clinically important hemodynamic effect in man is orthostatic hypotension, which can often be profound. A study by Taylor et al,[53] in which 62 patients with acute myocardial infarction were treated with bretylium, demonstrated hypotension to be a common finding. In one third of their patients, the drug had to be discontinued as a result of this adverse effect. Other investigators did not find this to be a problem, especially when their patients remained supine.[54,55] The hypotension probably results from adrenergic neuronal blockade, but its mechanism is not fully understood.

In summary, the positive inotropic effect of bretylium, although unique, is transient and probably of little clinical importance in most situations. The subsequent persistent decrease in blood pressure, especially in the upright position, is much more clinically relevant. It is well tolerated by many patients, but can lead to severe consequences, especially in those patients with low or fixed cardiac output on the basis of valvular heart disease or severe LV dysfunction. It must be used with care in these situations.

Disopyramide

Disopyramide has a negative inotropic effect, both in in vitro experiments using isolated cardiac muscle[56] and in studies in intact animals.[9] In one recent study in unanesthetized dogs,[9] intravenous disopyramide produced dose-related decreases in LV peak dP/dt and stroke volume and significant increases in heart rate, systemic vascular resistance and blood pressure. These changes occurred within 1 minute of injection and persisted for about 30 minutes. No significant change in cardiac output was observed. The investigators believed the changes were to a degree that could produce clinically important adverse effects in man.

These concerns have been shown to be well founded in many studies of disopyramide in man[44,57–69] and are expressed in several recent reviews.[70,71] Almost all studies show that disopyramide exerts a negative inotropic effect[44,57–63,69,72] in association with a direct effect to increase systemic vascular resistance.[44,58–61,63,73] The only differences from study to study have been differences in the severity of these changes, and this variation probably reflects differences in the patients being evaluated. The hemodynamic changes observed included increases in systemic blood pressure, decreases

in cardiac index and stroke volume, and increases in intracardiac filling pressures.

Disopyramide causes small but significant increases in LV filling pressures and decreases in cardiac index in normal subjects[62] and in patients with poor LV function, the changes are even more remarkable.[58–60,63] Occasional dramatic decreases in cardiac output associated with severe hypotension have been noted.[60]

Studies of oral disopyramide indicate that the cardiac depressant effects of this drug are not unique to the intravenous preparation.[65–69] Reports of cardiogenic shock[67,68] and electromechanical dissociation[66] due to disopyramide demonstrate the potential for disastrous results associated with the use of this drug in patients with severe abnormalities of LV function.

Podrid et al[65] describe the clinical follow-up study of 100 patients who began taking disopyramide for the control of arrhythmias; they emphasize the importance of careful patient selection before the use of this drug. In their group of patients, 62 were taking disopyramide for only several days and the remainder were treated on a long-term basis with 9 months of follow-up evaluations. In 16 of the original 100 patients, clinical congestive heart failure developed during this period, in 3 during the first 48 hours and in 13 during long-term treatment, usually within 3 weeks of beginning the drug. In 55% of the patients with a history of congestive heart failure, congestive heart failure again developed with disopyramide therapy. Only 2 patients without such a history had congestive heart failure while taking this drug.

Disopyramide combines a significant negative inotropic effect with a peripheral vasoconstrictive effect that results in some adverse hemodynamic effects in most patients. The changes are of little clinical consequence in patients with well-preserved LV function; however, patients with LV dysfunction and a history of congestive heart failure have a high propensity for clinical deterioration, and disopyramide should be avoided in these patients.

Phenytoin

Two studies of the effects of phenytoin (formerly diphenylhydantoin) on the isometric force of contraction of isolated cardiac muscle[1,74] have shown a significant negative inotropic effect. In one of these,[1] phenytoin had the most significant depressant effect on contractility of any of the drugs evaluated, including propranolol.

Studies in animals have generally shown 2 primary effects: a mild, transient, negative inotropic effect and a transient decrease in blood pressure.[17,74,75] The decrease in contractility appeared to be dose-related[17,74,75] and lasted for 3[75] to 60 minutes.[74] This effect was probably clinically important only at large doses. A transient decrease in systemic arterial pressure was observed in most studies using intravenous phenytoin[75,76] and appears to be due primarily to peripheral vasodilation.[74] This effect is unchanged by denervation[75] or beta blockade[74] and is considered due to a direct action of phenytoin on the peripheral vasculature. Sanbar et al[76] demonstrated that the degree of hypotension after the administration of phenytoin was not only related to total dose, but more importantly, to the rate of administration of the drug. This may account for many of the differences seen between studies in both animals and man.

Findings of hemodynamic studies of phenytoin in man agree with those of animal investigations. In general, the use of intravenous phenytoin has been associated with a transient, mild, negative inotropic effect[30,77] and, occasionally, a brief decrease in systemic blood pressure.[30,78] However, some studies found no evidence of decreased contractility[79] or change in blood pressure.[77,79] These differences may be related to the population studied or the rate of administration of the drug, as demonstrated by Mierzwiak et al.[80]

Most of these studies have been done in patients with well-preserved LV function and relatively small doses of phenytoin were used. When hemodynamic effects occurred, they were so mild and so transient as to be clinically inconsequential. High doses of this agent in patients with severely compromised LV function could result in more apparent detrimental clinical effects.

A report by Mercer and Osborne[78] of 6 years of clinical experience with phenytoin for the treatment of arrhythmias supports the conclusions of the hemodynamic studies. Over this period, intravenous phenytoin was used to treat 774 episodes of arrhythmia. They describe only a rare occurrence of mild, transient hypotension and no precipitation or exacerbation of congestive heart failure. The drug was administered during monitoring of intracardiac pressures in >130 of these episodes and there were no significant effects observed on pulmonary artery pressure.

In summary, phenytoin in the doses most often used is safe and well tolerated by most patients. It exhibits a mild negative inotropic effect that is generally of little clinical significance even in patients with moderate degrees of LV dysfunction. The hypotension produced by the intravenous infusion of this drug appears to be related not only to total dose, but more importantly, to the rate of administration. It can be almost completely avoided by using slow infusion rates (<25 mg/min) and by avoiding rapid bolus injections. Phenytoin has produced few untoward hemodynamic responses during its long period of clinical use.

Calcium Antagonists

There are a number of recent reviews of the use of the calcium antagonists.[70,71,81–84] These drugs demonstrate a great interplay of direct and indirect hemodynamic effects. The overall outcome in any subject is difficult to predict and depends on the relative contribution of these direct effects and reflex responses. This fact makes comparison of one study to the next and the interpretation of their results difficult. Nevertheless, certain responses are consistently observed during the use of these drugs.

In vitro studies of perfused hearts and isolated cardiac muscle have shown negative inotropic and chronotropic effects of all the calcium antagonists in general use (nifedipine, verapamil and diltiazem);[85] only the degree of these effects varied from agent to agent.

In animals, calcium antagonists cause a dose-related decrease in systemic vascular resistance and blood pressure[86–91] owing to a direct peripheral vasodilating action. The effects on contractility are not quite as consistent. In vivo studies with diltiazem have generally shown no significant change in LV peak dP/dt;[85,86] nifedipine has produced an improvement[89] and verapamil has generally caused some decrease.[85,90,91]

The chronotropic effects of diltiazem and verapamil in animals have varied from study to study. Most investigators have shown a dose-related decrease in heart rate,[88,90,91] some have demonstrated no change,[86,89] and one showed an increase in heart rate for both of these agents as well as for nifedipine.[85] An interesting study by Bourassa et al[86] highlights the interplay of the direct and reflex effects of these drugs. Intravenous diltiazem administered to anesthetized dogs produced no change in heart rate despite a 30% decrease in mean aortic pressure. When aortic pressure was returned to control levels by mechanical constriction, the resulting heart rate decreased to 85% of the control value. Their conclusion was that the direct negative chronotropic effect of diltiazem was masked by the reflex increase in heart rate resulting from the drug-induced decrease in systemic arterial blood pressure.

Almost all studies in man show a substantial decrease in blood pressure and systemic vascular resistance immediately after intravenous administration[86,92–102] and demonstrate that this effect is not abolished by beta-adrenergic blockade.[101,102] Similar results have been observed with a different time course after oral administration.[103–105] Most investigators have found a decrease in LV peak dP/dt after the administration of a calcium antagonist[93,97,98,101] and many have reported an increase in LV end-diastolic pressure.[93,96–98] In spite of these findings, cardiac index increased in most studies in which it was evaluated[92,94–96,98,103] and was found to decrease or remain unchanged primarily when beta-blocking drugs were given in conjunction with the calcium antagonists.[101,102,105]

The extent of these hemodynamic changes at the standard doses used have generally been small and well tolerated. However, the potential for clinical deterioration in some patients with severe LV dysfunction who are treated with calcium antagonists does exist.[99]

The effects of the calcium antagonists on heart rate in man have been studied in several investigations, with variable results.[86,92–99,101–105] In most, diltiazem and verapamil produced no consistent change in heart rate.[92,94,96,97,99,104] Others have shown a slight increase in heart rate[93,95,98,103] and some have shown a decrease,[86] especially in conjunction with beta-blocking drugs.[101,105] Most of these changes have been small and of little clinical significance.

In general, in man verapamil appears to have a greater overall negative chronotropic effect than diltiazem, and nifedipine usually produces a small increase in heart rate due to its potent peripheral vasodilating effect. In any given patient, however, the effect on heart rate for any of these agents is difficult to predict.

In summary, the hemodynamic effects of the calcium antagonists result from a complicated interaction of direct and reflex effects. All of the agents produce peripheral vasodilation by direct action on the vasculature. This produces a reflex increase in sympathetic tone, leading to an increase in myocardial contractility and heart rate. These positive inotropic and chronotropic effects may be offset by direct negative inotropic and chronotropic effects. The net result depends on the particular agent used, the particular patient involved and the interplay of the various factors. In most patients, the calcium antagonists do not exert serious adverse hemodynamic effects. However, some patients with severe LV dysfunction may have clinical deterioration. In this group of patients calcium antagonists must be used with caution.

Amiodarone

Several reviews[70,71,106,107] and a number of clinical studies[108–114] suggest that the hemodynamic effects of amiodarone are related to its total dose as well as to the baseline cardiovascular state of the patient in whom it is used. The use of intravenous amiodarone has been assessed in patients with various degrees of LV dysfunction. In most of these, a dose of 5 mg/kg of amiodarone was given as a bolus,[108,109,113,114] and in some this was followed by a constant infusion.[109,113] A decrease in arterial pressure was noted in most patients,[108,113,114] but an occasional investigation revealed no significant change in this measurement.[109] The rate of drug administration correlated with the decrease in systemic blood pressure in some patients.[108] Although most data have shown that the decrease in arterial pressure is due to peripheral vasodilation with an associated decrease in systemic vascular resistance,[70,71,106–108] some studies have demonstrated little or no change.[109,114] Most studies have also revealed a moderate decrease in heart rate associated with intravenous administration of amiodarone.[109,114]

Few studies have made careful measurements of changes in myocardial contractility after administration of intravenous amiodarone. A study in intact dogs demonstrated that a dose of 10 mg/kg had a negative inotropic effect as measured by a decrease in LV peak dP/dt.[115] Studies in patients using smaller doses of amiodarone have shown variable results. Some have shown increases in cardiac index and decreases in LV end-diastolic pressure,[108] and others have shown slight decreases in cardiac index and small increases in pulmonary capillary wedge pressure.[109,114] The differences may well be a result of differences in the baseline LV function of those patients being evaluated. In these intravenous studies, no exacerbation or precipitation of clinical congestive heart failure was seen, even in patients with severe LV dysfunction.[108,109,113] However, an occasional patient did have severe hypotension that required temporary pressor support.[114]

Investigations of oral amiodarone have demonstrated similar results.[110–112] Doses of amiodarone of 200 to 1,200 mg/day did not produce the deterioration or appearance of congestive heart failure, even in patients with severe LV dysfunction followed for as long as 22 months.[111] No detailed hemodynamic data are supplied in these studies, but in general, the drug appeared well

tolerated. In one study 3 deaths from progressive congestive heart failure were reported during 13 months of follow-up, but the association with amiodarone therapy in those patients was not described.[112] Some investigators have also found a modest negative chronotropic effect of oral amiodarone.[110]

Overall, both oral and intravenous amiodarone is well tolerated in most patients. It does exhibit mild negative inotropic and chronotropic effects and its intravenous administration produces peripheral vasodilation with a decrease in arterial blood pressure. In most situations, these effects are not of clinical importance. However, with high doses or rapid infusion rates and in patients with severe LV dysfunction, the potential for significant hypotension does exist.

Mexiletine and Tocainide

Investigations on the hemodynamic effects of mexiletine[116–122] and tocainide[123–128] have generally shown similar results. The use of intravenous mexiletine in animals[118] and in man[116,117,120–122] has produced few significant hemodynamic effects. Small decreases in arterial pressure and LV peak dP/dt and small increases in LV end-diastolic pressure have been observed in some studies,[118,120] but in almost all cases these have been so mild and transient as to be of no clinical significance. Cardiac output has generally remained unchanged. One study by Saunamäki[117] did include 2 patients who had a significant decrease in arterial blood pressure associated with a decrease in systemic vascular resistance and 2 other patients who had significant increases in pulmonary capillary wedge pressure. Even in these patients, no clinical deterioration was seen. The significant changes in these hemodynamic measurements after intravenous mexiletine administration in this investigation are unusual and may be related to the severe degree of LV dysfunction of those 4 patients before drug administration.

Kuhn et al[119] examined the hemodynamic effects of a single large dose of mexiletine administered orally to a group of patients with coronary artery disease. They found no clinically or statistically significant changes in systemic or pulmonary artery pressure or in cardiac output for up to 6 hours after the dose was given.

Tocainide also causes mild and usually clinically unimportant hemodynamic effects. The use of the drug intravenously produces small decreases in LV peak dP/dt[125,127] or small increases in LV end-diastolic[123] or pulmonary capillary wedge pressure.[127] Some investigators have also reported slight increases in systemic vascular resistance.[123,126] Measurements of cardiac output have generally shown no change before and after administration of the drug.[123,125,127]

Large doses of tocainide administered orally to anesthetized dogs produced decreases in LV peak dP/dt and aortic flow and increases in LV end-diastolic pressure.[124] Even these large doses produced only small to moderate effects and small doses produced no measurable hemodynamic changes. Oral tocainide in man has produced no significant hemodynamic effects even in patients with acute myocardial infarction,[126] and has not caused any change in echocardiographic dimensions when administered to patients with valvular heart disease.[128]

Overall, mexiletine and tocainide in both oral and intravenous form have been well-tolerated hemodynamically, even in patients with moderately severe LV dysfunction. They both have mild negative inotropic effects, but these have not been shown to be of clinical importance.

Encainide, Flecainide, Lorcainide

Hemodynamic evaluations of encainide, flecainide and lorcainide have been few, but their results are similar. Intravenous encainide given to patients with varying degrees of LV dysfunction produced little or no negative inotropic effect and had little or no effect on systemic vascular resistance.[129] Oral encainide similarly produced no significant change in radionuclide ejection fraction at rest or during treadmill exercise in a group of patients with fairly well preserved LV function.[130]

Flecainide has been less systematically evaluated. When administered intravenously to anesthetized pigs, decreases in LV peak dP/dt and cardiac output were observed and appeared to be dose-related.[131] In man, only oral flecainide has been studied and only its effects on echocardiographic parameters have been evaluated.[132–134] No detailed hemodynamic studies have been done. Nevertheless, these investigations showed oral flecainide to be well tolerated, without significant effects on blood pressure or echocardiographic measurements in patients with fairly well preserved LV function.[132–134] No clinical deterioration or change in exercise tolerance was observed.[134]

Intravenous lorcainide has been evaluated in more detail. It produces decreased contractility of isolated papillary muscles studied in vitro.[135] In vivo studies in dogs have shown that it causes transient decreases in LV peak dP/dt, systemic arterial blood pressure and systemic vascular resistance and, at high doses, occasionally produces significant increases in LV end-diastolic pressure.[135]

Studies of intravenous lorcainide administered to man have demonstrated small decreases in LV peak dP/dt[136] and cardiac output.[136,137] In the study by Meinertz et al,[136] angiographically determined LV ejection fraction decreased by a small amount in almost all patients after intravenous lorcainide was administered. In all of these investigations, the changes were small and of little clinical significance in the groups of patients studied.

In summary, encainide, flecainide and lorcainide appear to be well tolerated hemodynamically when administered to patients with fairly well preserved LV function. However, all exert a mild negative inotropic effect and must be used with care in patients with severely compromised LV contractility or poorly compensated congestive heart failure. The dearth of systematic hemodynamic studies in these groups of patients makes it impossible to realistically assess the risk of using these agents in such patients. Certainly, the theoretical risk of clinical deterioration exists and appropriate caution must be exercised.

Conclusion

Antiarrhythmic drugs are often used in patients with organic heart disease who have varying degrees of LV dysfunction and who have overt or compensated congestive heart failure. Most antiarrhythmic agents, with the exception of bretylium, have mild or moderate negative inotropic effects when examined by sensitive methods. In practice, however, most of these drugs, with the possible exception of disopyramide, when used at standard doses rarely produce clinically important hemodynamic effects. However, in patients with severe LV dysfunction or when high doses are required, the hemodynamic effects may become clinically important. In these circumstances, the basic characteristics of each agent must be examined to choose the most appropriate drug.

Clinical Profiles of Newer Class I Antiarrhythmic Agents—Tocainide, Mexiletine, Encainide, Flecainide and Lorcainide

ANTHONY POTTAGE, MRCP

New class I antiarrhythmic drugs differ in potency, adverse effects and pharmacokinetics. Encainide and flecainide can totally suppress arrhythmias in some patients, but arrhythmia induction can also occur. At effective dose levels, neurologic and gastrointestinal adverse effects are uncommon. Flecainide pharmacokinetics are suitable for oral use but encainide disposition is complex with variable bioavailability and active metabolites that contribute substantially to activity. Lorcainide is also potent, but neurologic adverse effects are common and dose-dependent bioavailability and an active metabolite may complicate long-term oral therapy. Tocainide and mexiletine can suppress arrhythmias in acute myocardial infarction, during convalescence from myocardial infarction and in patients with arrhythmias resistant to other therapy. Dose-related neurologic and gastrointestinal adverse effects are common, but hemodynamic effects are minor and arrhythmia induction is rare. Tocainide disposition is reasonably predictable and stable in patients, but mexiletine disposition is less so because of variation in distribution and clearance. Although all of the newer agents have some disadvantages, their availability should increase the likelihood of success in the high-risk patient.

(Am J Cardiol 1983;52:24C–31C)

All antiarrhythmic agents available for general use in the United States—lidocaine, quinidine, procainamide, disopyramide and beta-adrenergic antagonists—have properties that limit their clinical value. Although no drug totally suppresses arrhythmias in all patients, all are accepted as having useful antiarrhythmic activity. Other factors, such as pharmacokinetic properties inappropriate for oral use, impairment of intracardiac conduction, negative inotropic effects, and dose-related or idiosyncratic adverse effects, are the major limitations to their use.

Identification of these problems has resulted in a search for new antiarrhythmic drugs that offer equal or greater potency with fewer clinical limitations, and a number of agents are undergoing active development. The agents described in this review—tocainide, mexiletine, encainide, flecainide, and lorcainide—are class I drugs that reduce the rate of increase of Purkinje and ventricular action potentials by inhibiting the fast sodium channel.[1]

Tocainide

Tocainide is an analog of lidocaine that has similar antiarrhythmic, hemodynamic and electrophysiologic effects, but with pharmacokinetic properties suitable for oral use.

From the Astra Clinical Research Unit, Edinburgh, Scotland.

Electrophysiologic and hemodynamic effects: Tocainide shortens action potential duration[2] and the effective refractory periods of the atria, atrioventricular node and ventricles.[3] It has little effect on sinus nodal automaticity or intracardiac conduction,[4] even in patients pretreated with a beta-adrenergic antagonist.[5] Although PR and QRS intervals are usually unchanged, tocainide may reduce the QT interval.[6] Cardiac hemodynamic effects are minor, even in patients with moderate left ventricular dysfunction[7] and those also receiving a beta antagonist.[5] In the acute stages of myocardial infarction (MI), the hemodynamic effects of tocainide are quantitatively similar to those of lidocaine and are determined by the rate of administration and by plasma concentration.[8]

Antiarrhythmic effects: Table I is a list of the effects of tocainide on the frequency of ventricular premature complexes (VPCs) as reported in a number of studies. The percentage of patients who showed >70% VPC suppression varied from 11 to 75% (mean 58), and in those who responded the VPC frequency decreased by 86 to 94%. In 1 study, concentrations <3.5 μg/ml produced <50% VPC suppression, and concentrations of about 8.5 μg/ml approximately 90% suppression. There was little further increase in activity with higher concentrations.[9] A similar relation between concentration and response was reported by Roden et al.[19]

TABLE I Oral Tocainide—Effects on Frequency of Ventricular Premature Complexes in Patients with Chronic Ventricular Arrhythmias

* >70% ventricular premature complex suppression.
VPC = ventricular premature complexes.

In 17 patients treated with tocainide for up to 27 months, symptoms were abolished in 7 of 9 with sustained ventricular tachycardia (VT), ventricular fibrillation (VF), or both and in 1 of 3 with symptomatic nonsustained VT.[20] In a similar group, tocainide abolished the arrhythmia in 14 of 21 patients with recurrent VT, and in 8 of the 11 in which the arrhythmia was symptomatic.[13] Tocainide can be effective in patients with arrhythmias unresponsive to other oral therapy,[19,21,22] and a response to lidocaine may predict responsiveness to tocainide.[19]

Since 1974, oral tocainide has been available in the United States for emergency use in patients unresponsive to or intolerant of quinidine, procainamide, propranolol and, recently, disopyramide. To qualify for treatment, patients had to have sustained VT, paroxysmal VT or VF, R-on-T VPCs, multifocal VPCs (>6/min) or symptomatic unifocal VPCs (>15/min). Data on the initial response to tocainide are available for 1,236 patients (Assaykeen T, Pottage A, Irvin JD, Schrogie JJ: unpublished observations). Fifty-six percent had >75% suppression of VPCs, 27% had <75% suppression and 17% had no response or an increase in arrhythmia frequency. Of 1,206 patients discharged from the hospital taking tocainide, 509 gave a history of emergency hospital admission for VT/VF, 390 a history of emergency cardioversion and 407 a history of syncope before enrollment in the program. Eighty-seven patients were readmitted to the hospital for VT/VF while receiving treatment with tocainide, 60 required cardioversion and 89 reported syncopal attacks.

In acute MI, tocainide suppresses "warning" arrhythmias with activity similar to that of lidocaine.[23] Prophylactic tocainide can suppress VT and frequent (>30/hour) VPCs in the first 24 hours of coronary care unit admission for MI[24,25] (Fig. 1). When given over a 6-month period after MI, oral tocainide prevents the increase in VPC frequency that occurs during mobilization.[26]

Pharmacokinetics and dosage regimens: Tocainide differs from lidocaine in that it has pharmacokinetic properties suitable for oral use (Table II). Its bioavailability is high, indicating little presystemic elimination, and absorption is rapid even in patients with acute MI.[27] Absorption is not dose-dependent and although the rate is reduced by food, the extent of absorption is unchanged.[28] Tocainide is rapidly distributed, with a total apparent volume of distribution of 2 to 4 liters/kg. There is little binding to plasma proteins (10 to 20%) and tocainide, unlike lidocaine, does not bind to alpha 1-acid glycoprotein.[29] Elimination is not dose-dependent and occurs by both renal excretion of unchanged drug (approximately 40%) and hepatic metabolism. The mean systemic clearance is about 120 ml/min in patients with chronic ventricular arrhythmias (Fig. 2) and the mean half-life is approximately 15 hours.[9–11,18,27] Tocainide clearance decreases predictably in patients with renal dysfunction, the mean half-life increasing to approximately 30 hours and the

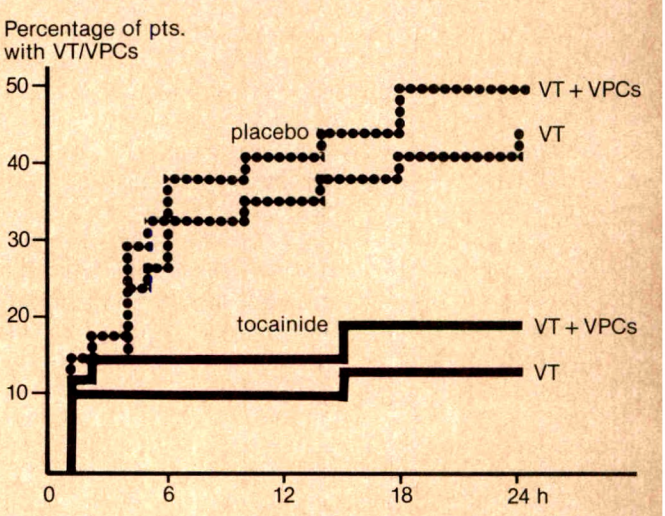

FIGURE 1. Cumulative incidence of ventricular tachycardia (VT) and frequent ventricular premature complexes (VPCs; >30 beats/min) over the first 24 hours of hospital admission in 31 patients with acute myocardial infarction given tocainide (750 mg intravenously, 800 mg orally then 400 mg every 8 hours) and in 34 given placebo. Reproduced from Rydén et al.[25] with permission of the publisher.

TABLE II Pharmacokinetic Properties of New Class I Antiarrhythmic Drugs

Drug	Bioavailability	Approximate Half-Life (hours)	Approximate Distribution Volume (liters)	Total Clearance (ml/min/kg)	Major Route of Elimination	Active Metabolites
Tocainide	95%	15	200	2.4	Metabolic/renal	No
Mexiletine	85%	11	500	6.5	Metabolic	No
Encainide	42%*	3	200‡	13.2	Metabolic*	Yes
Flecainide	95%	20	. . .	. . .	Metabolic	. . .
Lorcainide	. . .†	8	900	>15.0	Metabolic	Yes

* Probably dose-dependent.
† Dose-dependent.
‡ Value derived from half-life and clearance.

mean total clearance decreasing by about 50% (Fig. 2). The effects of partial renal dysfunction (creatinine clearance 10 to 55 ml/min) are intermediate.[30] Although tocainide metabolites (N-carboxytocainide glucuronide and lactoxylidide) may accumulate in renal failure, they have no significant pharmacologic activity.[31] In chronic liver disease, tocainide elimination is usually only slightly impaired, although significant prolongation of the half-life can occur with acute hepatic necrosis.[32] There appear to be no important pharmacokinetic interactions between tocainide and metoprolol (Granath, A: unpublished observations), digoxin,[12] phenobarbitone, clofibrate, or salicylamide.[33]

The suggested optimal range for tocainide plasma concentrations is 3.5 to 8.5 μg/ml tocainide base (4 to 10 μg/ml tocainide hydrochloride). In most patients, concentrations within this range can be achieved with a dosage of 1,200 to 1,800 mg/day given orally in divided doses every 8 or 12 hours. Tocainide plasma concentrations are relatively stable over long periods in patients with chronic ventricular arrhythmias.[20] However, if dose requirements alter as a result of changes in renal function, plasma concentration monitoring may be helpful to adjust dosage as the relation between dose and steady-state concentration is linear, and tocainide metabolites are not active. Doses of as much as 3,200 mg/day have been used in some patients with resistant arrhythmias, although the incidence of adverse effects is high.[21] Combined intravenous and oral loading doses have been described for emergency use.[23,25]

Adverse effects: The most common dose-related adverse effects in 943 patients given oral tocainide were dizziness (12.5%), paresthesia (6.5%), tremor (5.9%), nausea (14.3%), vomiting (5%) and sweating (5%); in 1 study, adverse effects of this type were noted in about 25% of patients with plasma tocainide concentrations >11 μg/ml.[19] Dose-related adverse effects tend to occur early in the course of treatment and to decrease in frequency and severity over time. They can be minimized by drug administration with food or by taking smaller doses more frequently.[21] Rashes have been reported in 1 to 3% of patients, but other hypersensitivity reactions, convulsions and arrhythmia induction are rare.[34–36]

Mexiletine

Mexiletine is a potent local anesthetic with electrophysiologic and hemodynamic properties similar to those of lidocaine and tocainide.[37,38]

Oral mexiletine and procainamide have similar potency in patients with chronic ventricular arrhythmias.[39] Breithardt et al[40] reported that oral disopyramide was more effective when both mexiletine and procainamide were given at a dose of 600 mg/day, but the difference disappeared when the mexiletine dose was increased. Other studies have confirmed the efficacy of mexiletine in patients with symptomatic arrhythmias not controlled with other therapy.[41–43] In acute MI, intravenous mexiletine may be more effective than lidocaine in suppressing VPCs and VT;[44] prophylactic oral mexiletine suppresses VPCs and VT in both coronary care unit populations[45] and patients treated at home.[46] However, Chamberlain et al[47] reported that of 181 patients recovering from MI, although oral mexiletine significantly reduced the frequency of VPCs 1 and

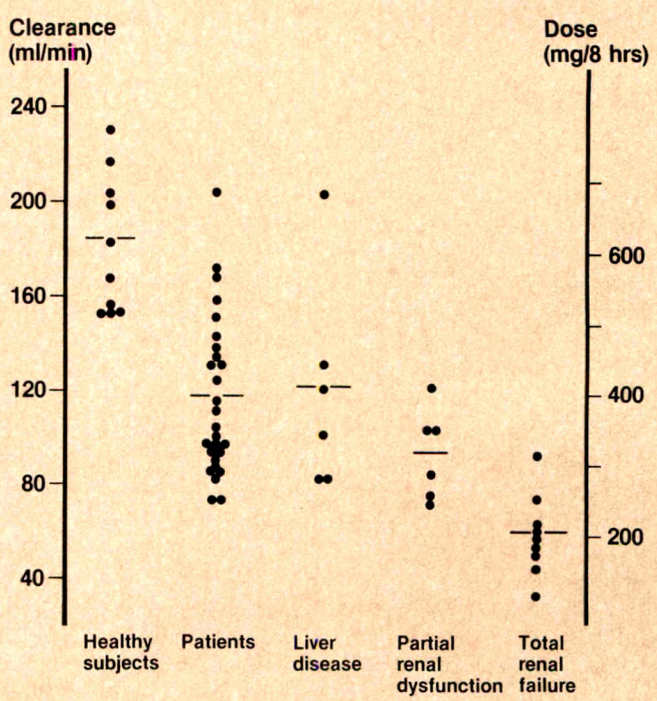

FIGURE 2. Total systemic tocainide clearance (mean shown by vertical bars) and doses (milligrams of tocainide hydrochloride every 8 hours) required to produce a mean steady-state plasma concentration of 6 μg/ml in healthy subjects and patients with chronic ventricular arrhythmias, liver disease and renal dysfunction. Data taken from references 9, 20, 27, 28, 30 and 32.

3 months after inclusion, and the incidence of couplets at 1 month, there was no significant effect on the incidence of VT or R on T VPCs.

Mexiletine differs from both lidocaine and tocainide in its pharmacokinetic properties (Table II). In contrast to lidocaine, it is well absorbed after oral administration and has a long half-life.[48] In contrast to tocainide, it is widely distributed and eliminated mainly by hepatic metabolism. The long half-life of mexiletine results mainly from extensive distribution, that of tocainide from low systemic clearance. Mexiletine absorption is delayed in patients with MI and by narcotics;[48] microsomal enzyme-inducing agents accelerate elimination.[49] Plasma mexiletine kinetics show little change in patients with renal failure,[50] but elimination is significantly impaired in liver disease.[51]

Plasma mexiletine concentrations of 1 to 2 μg/ml are considered optimal[52] and can normally be achieved with oral doses of 200 to 300 mg every 6 to 8 hours. There is considerable interindividual variation in steady-state plasma concentrations, which can vary 5- to 8-fold with a given dose.[52] This is presumably due to the intrinsic variation associated with high clearance and extensive distribution. Large loading doses are necessary to achieve effective levels quickly because of extensive distribution, and the doses required may be poorly tolerated.

Common dose-related adverse effects are neurologic or gastrointestinal and tend to occur early during therapy. In 1 study of 156 patients, minor adverse effects were noted in association with 30% of plasma mexiletine concentrations >2 μg/ml and severe adverse effects (bradycardia, hypotension, atrioventricular dissociation, vomiting and confusion) with 19% of such concentrations.[52]

Encainide

Encainide is a potent antiarrhythmic, structurally unrelated to other agents, that can be given both orally and intravenously. In vitro, encainide markedly reduces the action potential rate of increase, with no effect on the effective refractory period and minimal shortening of action potential duration.[53] In man, encainide prolongs His-Purkinje conduction and PR, HV and QRS intervals, usually with little change in sinus nodal recovery time, AH intervals or effective refractory periods.[54–58] A 10% increase in QT interval was noted in 1 study with intravenous encainide,[54] but not in others and not during short-term oral therapy.[55] Prolongation of the effective refractory period and QT interval during long-term therapy may be due to accumulation of an active metabolite.[56] Encainide produces little depression of cardiac hemodynamics in the absence of cardiac failure.[57,58]

Encainide is very potent and total abolition of arrhythmias has been recorded in 44 to 90% of patients given the drug on a short-term basis.[57,59] Ten responding patients from 1 short-term study continued receiving therapy, with satisfactory arrhythmia control in all patients for 6 to 12 months (mean 8).[57] However, in another study, long-term encainide therapy was evaluated in 38 patients with recurrent, symptomat VT; in 11, arrhythmias recurred within 1 month starting therapy.[60] Suppression of supraventricul extrasystoles and paroxysmal atrial tachycardia has al been reported.[54]

Encainide absorption is variable, probably becau of saturable presystemic elimination.[61] The total sy temic clearance is high but also variable, and the hal life is short (Table II). In 1 study, steady-state plasm concentrations were not linearly related to dos suggesting dose-dependent elimination.[57] Encainide extensively metabolized and 2 highly active metabolit accumulate to higher levels than the parent drug duri long-term therapy.[62] The effective dose has been r ported as 75 to 300 mg/day, given in divided doses eve 4 to 6 hours,[57,60,61] although frequent dosing may be le important during long-term therapy because of m tabolite accumulation. Antiarrhythmic plasma co centrations of encainide vary as much as 50-fold[61] an optimal concentrations for the metabolites are u known. Dosage should be adjusted on the basis of r sponse (arrhythmia suppression, QRS widening) an tolerance.[60]

Encainide is usually very well tolerated, and the rat of effective to toxic plasma concentrations is high.[60,] Dose-related adverse effects, usually neurologic o rarely, gastrointestinal, are uncommon at effective do levels.[54,59,60] However, induction of polymorphic VT h been reported in the absence of QT prolongation,[63] an in 1 series the incidence in patients with a history recurrent VT/VF was 11%.[64]

Flecainide

Flecainide is a potent class I agent with some add tional effects consistent with class III activity. In vit studies have shown delayed repolarization in canin ventricular muscle, and significant prolongation of i tracardiac monophasic action potentials occurs man.[65] Flecainide produces concentration-related i creases in PR, QRS and QT intervals[66] and prolongs t ventricular effective refractory period.[67] No major h modynamic changes have been found with antia rhythmic oral doses,[66] but minor negative inotrop effects occur during intravenous infusion.[68]

Flecainide produces marked suppression of ventri ular arrhythmias. In a dose-ranging study in 11 patien with refractory chronic arrhythmias, 8 with recurre VT, oral flecainide produced total suppression of VP in 6, (97% suppression overall) and total suppression VT during the initial evaluation. Effective plasm concentrations ranged from 245 to 980 ng/ml with dos of 100 to 300 mg every 12 hours. Nine patients continue to have substantial arrhythmia suppression during 1 11 months (mean 6.6) of continued therapy.[66] Oth short- and long-term studies with oral flecainide ha produced similar findings.[69–71]

Flecainide is well absorbed after oral administratio and has a long plasma half-life[66] (Table II). Adver effects appear to be minor (dizziness and blurring vision) and infrequent with oral doses that produce si nificant arrhythmia suppression.[65,69,70] Transient di

ziness and circumoral paresthesia have been reported after intravenous administration.[66] In 1 study, a paradoxical increase in arrhythmia frequency was noted in 4 of 11 patients shortly after starting and after withdrawing oral flecainide;[66] QT prolongation with induction of VT has also been reported.[72]

Lorcainide

Lorcainide is a local anesthetic that reduces action potential duration, but prolongs the effective refractory period. In man, lorcainide prolongs PR and QRS intervals, slowing intraventricular conduction dose-dependently.[73] Accessory pathway conduction and refractory periods are also prolonged and depression of sinus nodal function has been reported in sinoatrial disease.[74] Oral lorcainide produces little hemodynamic effect, but moderate negative inotropic effects have been reported with intravenous administration.[75]

Lorcainide is a potent antiarrhythmic, with activity against supraventricular as well as ventricular arrhythmias.[73,76] In 1 study in 10 patients with chronic ventricular arrhythmias, lorcainide (100 mg every 12 hours) produced 82 ± 20% VPC suppression compared with placebo.[77] In other studies, 9 of 15 patients had "significant" VPC suppression after intravenous doses chosen to give plasma concentrations of 200 or 300 ng/ml;[78] total suppression of recurrent VT/VF resistant to other drugs occurred in 6 of 7 patients given 100 mg every 8 to 12 hours.[79] In 20 patients treated for 6 months during recovery from MI, arrhythmia suppression appeared to increase progressively, with a 92% reduction overall at the end of the study.[80]

Lorcainide shows high hepatic clearance and saturable presystemic elimination, the bioavailability increasing with increasing oral dosage. It is extensively distributed and the half-life is variable (mean about 8 hours) (Table II).[81] One metabolite, norlorcainide, has antiarrhythmic activity and a half-life of approximately 20 hours.[82] Norlorcainide levels are low after short-term intravenous administration,[78] but significant accumulation occurs after repeated doses and plasma levels eventually exceed those of the parent drug.[77] Optimal plasma concentrations for lorcainide are poorly defined and presumably vary with metabolite accumulation, but levels of 150 to 400 ng/ml are considered "therapeutic."[78,82] Oral dosage can be given twice daily.[77] Neurologic and gastrointestinal adverse effects are common at the start of treatment and sleep disturbances (vivid dreams) also occur frequently.[77,78]

Discussion

Electrophysiologic and antiarrhythmic effects: All of the above agents have class I antiarrhythmic activity, reducing the initial rate of increase (phase 0) of cardiac action potentials.[1] Their effects on other action potential characteristics vary, and a subdivision of the class has been proposed to take this into account.[83] In this scheme, class Ia agents are those with potent effects on phase 0, producing prolongation of action potential duration. Examples are quinidine, procainamide and disopyramide. Class Ib agents have less effect on phase 0 and tend to shorten action potential duration (lidocaine, tocainide, and mexiletine); class Ic agents have marked effects on phase 0 and produce little change in action potential duration (encainide, flecainide and lorcainide). The clinical value of this electrophysiologic classification remains to be established. The effects of individual drugs on the action potentials of different cardiac tissues vary considerably, and findings in 1 isolated preparation are unlikely to reflect total drug activity in the whole heart. In addition, active metabolites with electrophysiologic characteristics different from those of their parent drugs may be present in vivo (for example, encainide). Nevertheless, the subdivision does reflect some clinical differences between class I drugs. Class Ic agents produce striking suppression of ventricular arrhythmias, at least in short-term studies, whereas class Ia agents seem less potent, and class Ib agents even less potent. In addition, class Ia and Ic agents show activity against a wider range of arrhythmias, including those of supraventricular origin. Unfortunately, the marked potency of class Ic and Ia agents also seems to parallel an ability to induce serious ventricular arrhythmias in some patients.

With the exception of tocainide and mexiletine, all of the newer agents produce increases in PR and QRS duration at antiarrhythmic plasma concentrations. These changes may be quite marked, and monitoring of QRS prolongation has been suggested as a means of optimizing dosage with encainide. Despite this, the development of significant heart block is uncommon. QT prolongation seems least likely to occur with the class Ib agents, and a number of studies[3,6] have documented QT shortening with tocainide.

Hemodynamic effects: Although experience of long-term oral therapy is limited with some of the newer agents, the hemodynamic effects of the drugs appear minor. Some negative inotropic effects occur after intravenous administration, and with lorcainide and tocainide, these appear to be related to the rate of administration as well as to the dose given. However, the long-term effects of the agents with active metabolites are not predictable on the basis of short-term intravenous exposure, and the hemodynamic effects of the active metabolites are largely unknown.

Pharmacokinetic properties: Pharmacokinetic properties play a particularly important role in determining the clinical value of antiarrhythmic drugs. Drug effects are generally related to plasma concentration; for safe long-term therapy, concentrations should be predictably related to dose and should be stable in the patient to avoid failure of therapy or toxicity. These are difficult goals to achieve, as antiarrhythmic drugs are used in a patient group with widely varying cardiac, renal and hepatic function. Multiple drug therapy, with the potential for drug interaction, is a frequent additional complication.

Some of the newer class I agents have pharmacokinetic properties (Table II) that may, in theory, be troublesome. The bioavailability of lorcainide and encainide is highly variable, and with lorcainide it is known to be dose-dependent. Absorption is likely to be un-

predictable, and increasing dosage may produce disproportionate increases in plasma concentration with unexpected toxicity. This may be less troublesome with encainide than with lorcainide because the ratio of toxic to effective encainide concentrations appears to be high.

Active metabolites contribute to the effects of lorcainide and encainide after repeated dosage. They may not make a major contribution at the start of treatment and, as a result, the effects of short- and long-term therapy may differ. Similarly, intravenous and oral therapy result in different metabolite concentrations initially, as the metabolites are generated more rapidly with oral therapy on "first pass" through the liver. Concentrations of active metabolites should be taken into account if plasma concentration monitoring is used to optimize dosage; at present, the quantitative effects and therapeutic ranges of these metabolites are poorly defined. Liver disease and drug inhibition or induction of hepatic microsomal enzyme activity may influence the formation of active metabolites and overall drug activity, but this area also remains to be investigated.

Many patients with arrhythmias have intrinsically unstable cardiac, renal or hepatic function. In theory, absorption and elimination of drugs with high metabolic clearance (such as encainide or lorcainide) may be altered in patients with liver disease and perhaps those with cardiac failure. Liver disease significantly impairs the elimination of the high-clearance drug mexiletine, although cardiac failure appears to have little effect. In contrast, tocainide elimination shows little change in chronic liver disease, but excretion is predictably impaired in patients with end-stage renal failure. Tocainide plasma concentrations are usually stable over long periods in patients with chronic arrhythmias, perhaps due to the availability of 2 routes of elimination (metabolic and renal), which compensate one another for day-to-day changes in excretory function. Cardiac failure appears to have little effect on tocainide disposition, and there is little binding to the $alpha_1$ acid glycoproteins that are known to alter the free fraction of lidocaine in acute MI.

All of the newer class I agents show prolonged activity after repeated dosage, allowing oral administration 2 to 4 times daily without the need for controlled-release dosage formulations. With encainide, continuous arrhythmia suppression with these dosage intervals relies on the accumulation of active metabolites with long half-lives, as the half-life of the parent drug is relatively short. Intravenous dosage forms are available for all the newer class I agents, although for those with long half-lives, complex loading regimens are necessary to achieve effective levels quickly and to avoid subsequent accumulation if intravenous administration is prolonged. With tocainide and mexiletine, combined oral and intravenous loading doses that circumvent this problem have been described for emergency use.[25,41]

Adverse effects: Dose-related neurologic and gastrointestinal adverse effects occur with all the newer class I agents, but with encainide and flecainide they appear to be minor and infrequent at dose levels that produce marked arrhythmia suppression. With the other agents, dose-related effects may be minimized by reducing the dose or rate of intravenous administration or by giving smaller doses more frequently. Serious adverse effects (agranulocytosis, pulmonary fibrosis, liver dysfunction and convulsions) have been reported with a number of agents, but are uncommon. Induction of ventricular arrhythmias can occur with all of the newer agents, although this phenomenon has been reported most frequently with encainide and flecainide.

Conclusions

The newer class I antiarrhythmic agents offer combinations of pharmacokinetic properties and electrophysiologic, antiarrhythmic and adverse effects that are different from those of the currently available drugs. None achieve the perhaps unrealistic goal of efficacy in all patients, complete freedom from adverse effects and appropriate pharmacokinetic properties for both intravenous and oral use. Encainide and flecainide are extremely potent and usually well tolerated, but their potency may carry a risk of arrhythmia induction. Dose-related neurologic and gastrointestinal adverse effects are common with the other agents, but more serious toxicity appears to be rare. Tocainide appears to have useful pharmacokinetic properties for predictable long-term use in a variety of different patient groups.

No two arrhythmias are the same, and no antiarrhythmic drug can be expected to suppress all arrhythmias, irrespective of underlying mechanism or etiology. Similarly, no drug can be expected to behave ideally in all patients, irrespective of age, clinical condition and other drug therapy. Faced with this degree of individual variation, there is clearly a need for more antiarrhythmic agents, each differing subtly in electrophysiologic effects and pharmacokinetic behavior. The newer class I agents are a step toward fulfilling this need and, by providing new combinations of properties, increase the options for individualization of therapy in the high-risk patient.

Effect of Antiarrhythmic Drugs on Mortality After Myocardial Infarction

CURT D. FURBERG, MD

The theoretical potential for a preventive or prophylactic effect of antiarrhythmic drugs (excluding beta blockers) in the treatment of coronary patients with ventricular arrhythmias has not been realized. Randomized controlled clinical trials conducted during the early hospital phase after an acute myocardial infarction as well as after discharge have not demonstrated an effect on patient survival.

Three possible explanations exist. First, treatment of ventricular arrhythmias does not improve prognosis. Although this explanation is supported by the overall trial results, it is contrary to massive evidence from animal, clinical and epidemiologic studies. Second, treatment of ventricular arrhythmias does prolong life but benefit has not been observed in the trials. Limitations in applied methods, including insufficient sample sizes, may have obscured a true favorable intervention effect. Third, control of ventricular arrhythmias helps some patients but harms others. Concomitant treatment with digitalis and diuretics and, possibly, arrhythmogenic properties of the investigational drugs themselves might have confounded the overall results.

The second in particular, but also the third explanation, are the most plausible. Only 1 of the 20 controlled clinical trials considered for this review required presence of ventricular arrhythmias as an entry criterion. All trials were small; the largest number of patients enrolled in a single trial was 610 and the highest number of deaths in a trial was 49.

To resolve the uncertainty, increased attention to methodologic issues, such as selection of appropriate study populations, intervention strategies and larger sample sizes, is required. Only then will it be possible to determine whether antiarrhythmic drugs exert a life-prolonging effect.

(Am J Cardiol 1983;52:32C–36C)

Ventricular arrhythmias are a major cause of death in patients with coronary heart disease. Electrocardiographic monitoring has enabled recognition and treatment of ventricular arrhythmias by a spectrum of agents that are more or less effective in controlling various rhythm disturbances. By suppressing the arrhythmias, these drugs can reduce symptoms associated with ventricular arrhythmias and, in addition, have the theoretical potential of preventing sudden arrhythmic deaths. This report critically reviews the evidence accumulated to date regarding the effect of antiarrhythmics on mortality, excluding beta-blocking agents in patients with myocardial infarction (MI).

Methods

This review considers clinical trials reported before March 1, 1983, in patients with a documented or suspected MI. Trials were included if they met the following criteria: (1) a total sample size of ≥100 enrollees, (2) random assignment of subjects to either a treatment or a control group, and (3) reporting of all-cause mortality.

From the Clinical Trials Branch, Federal Building, Room 216, National Heart, Lung, and Blood Institute, the National Institutes of Health, Bethesda, Maryland.

These criteria were chosen for important reasons. First, they were selected to limit this review to those trials that could possibly have had sufficient statistical power, as judged by sample size, to discern a clinically important benefit or trend. Moreover, a selection of a much larger number would have limited the review to very few trials. It is realized that a sample size in the thousands is often needed in a prevention trial to expose a treatment to a fair test. Many of the reviewed trials were not designed primarily to ascertain a drug effect on mortality. Second, the criteria were chosen to restrict the review to trials that incorporated randomization in their design, the best protection against treatment-allocation bias. Third, all-cause mortality was the preferred response variable to avoid the potential bias in determining cause-specific mortality. Total mortality data rely on a count without any element of judgment and allows straightforward comparisons across trials. Patients successfully resuscitated from ventricular fibrillation are not included among the deaths. As there is no available evidence that antiarrhythmic drugs favorably influence infarct size or exert a continued beneficial effect after treatment is terminated, only deaths that occurred during the defined intervention period are considered. To reduce the bias that may be introduced by differential withdrawal of patients in the analysis, all those randomized, regardless of level of compliance, have been included in the mortality estimates if the data were available. The exceptions

consist of 7 trials that did not report the outcome in patients with unconfirmed MI. Therefore, for all these reasons the figures given are sometimes different from those in published trial reports.

The trials have been divided into short-term and long-term studies, the former having a treatment period of ≤2 months. In the short-term trials that met the review criteria, treatment was usually started at the time of hospital admission for a suspected MI and continued for up to 6 weeks. In the long-term trials treatment was initiated before hospital discharge and continued for 3 to 24 months.

The proportion of deaths in each treatment group has been compared by a chi-square test. This only approximates a comparison of survival curves, but the results are usually similar. To enable comparison of the different trials in this review, while taking into account differences in control group mortality rates, the effect of treatment has in each case been standardized to the relative difference. The approximate 95% confidence limits for the relative risk were computed by the Cornfield method.[1] One can reasonably conclude that the *true* effect of treatment in a particular trial lies somewhere within the bounds of the confidence limits given.

Results

Short-term trials: Fourteen acute-phase trials[2–15] met the review criteria (Table I). The total number of patients enrolled into the studies ranged from 104 to 374. Six trials[3,5,6,9,11,13] excluded in their reporting randomized patients with unconfirmed MI. Fixed oral dosages of quinidine (1,200 mg/day) and procainamide (2 to 4 g/day) were each evaluated in 2 trials[2–5] and disopyramide (400 to 600 mg/day) was evaluated in 3 trials.[6–8] The length of the treatment phase in the trials using oral administration varied from 3 days to 6 weeks. Seven trials of lidocaine, 5 using an intravenous infusion[9–13] and 2 a single intramuscular injection[14,15] fulfilled the criteria. An initial injection was given, followed by intravenous infusion at a rate of 0.5 to 3 mg/min. The

intramuscular dose was 300 mg. Ten of the 14 short-term trials used a double-blind design (Table I).

The mortality results are shown in Table II and Figures 1 and 2. The number of deaths was relatively small in all trials. In 4 of the 7 studies that evaluated oral treatment, the mortality rate was lower in the treatment group compared with the control group. In 3 trials (1 of each of the drugs tested) there were fewer deaths among the control subjects compared with the patients given antiarrhythmics. Four of the lidocaine trials had a higher percent mortality rate in the treatment group and 2 of the trials had a lower rate. In the seventh trial, no deaths occurred during the treatment period. In none of the 14 short-term trials did the mortality difference reach statistical significance.

Adverse effects were fairly common and necessitated termination of treatment in many patients. At the end of the treatment phase the proportion of patients not receiving drugs varied from 10 to 40%. The antiarrhythmic effect of the agents was not evaluated and reported in a uniform or standardized manner. The suppression of frequent or complex ventricular premature beats was judged as substantial in 5 trials[4–6,10,13] and moderate in 4.[2,3,7,8] The effect was uncertain in 3 studies,[9,11,12] and 2 trials[14,15] did not provide information on suppression of ventricular premature beats.

Long-term trials: Only 6 trials[16–22] fulfilled the review criteria (Table III). Their sample sizes were also small, ranging from 146 to 568 patients. Randomized patients with unconfirmed MI were excluded from the analysis in 1 trial.[18] Fixed dosages of phenytoin (300 to 400 mg/day) were tested in 2 trials,[16,17] tocainide (600 to 1,200 mg/day) in 2[18,19] and mexiletine (600 to 750 mg/day) in 1 trial.[20] The sixth trial[21,22] differs from all other trials of antiarrhythmic drugs in that the dosage of the drug (aprindine) was determined by the suppression of ventricular arrhythmias and ranged from 100 to 200 mg/day. The intervention phases lasted 3 to 24 months. Five of the 6 trials were double-blind (Table III).

Two of the trials showed a trend in favor of active treatment; 3 had a reverse trend and in 1 trial, the mortality rate was the same in the 2 groups (Table IV, Fig. 3). No differences were statistically significant.

By the time of trial termination, the proportion of patients not taking active drugs ranged from 20 to 30%. The suppression of frequent or complex ventricular premature complexes was considered substantial in 4 trials,[16,18,19,22] moderate in 1[20] and unknown in 1 study.[17]

* p values computed for chi-square test comparing the proportion of deaths in each group.

In summary, 20 randomized controlled clinical trials of antiarrhythmic drugs in MI patients who met the review criteria have been published. The effect of 8 different agents on mortality was evaluated. More than 4,500 patients were enrolled into the trials and the outcome of the treatment was reported.

One would have expected 1 trial to have reached a p value of <0.05 by chance alone, but a statistically significant benefit was not observed in any trial. In fact, favorable and nonfavorable trends were equally common among the 20 trials.

Discussion

As in any clinical trial in which no statistically significant difference is observed, 3 explanations are possible. In the case of antiarrhythmics these are (1) control of ventricular arrhythmias with the agents used does not improve prognosis, (2) control of ventricular arrhythmias with these agents prolongs life, but this prolongation was not observed in the trials, and (3) treatment of ventricular arrhythmias with these agents helps some patients but harms others.

Control of ventricular arrhythmias does not improve prognosis: The findings from the reviewed trials support the explanation that control of ventricular arrhythmias does not improve prognosis. Although the trials were small, one would have expected that if control of ventricular arrhythmias prolongs life, more than half of the trials would show a trend in favor of active treatment.

On the other hand, research data reviewed in other reports in this symposium strongly support the view that suppression of ventricular arrhythmias should be beneficial. Moreover, extensive use of antiarrhythmic drugs among cardiac patients, which appears to be based on the clinical impression of many cardiologists, also is counter to the explanation that these drugs have no preventive effect.

Control of ventricular arrhythmias prolongs life but the prolongation was not observed in the trials: Limitations in the design and conduct of the reviewed trials could be used to argue the explanation that control of ventricular arrhythmias prolongs life, although this effect was not observed in the trials. The patient selection was less than optimal. In 19 of the 20 trials, patients were enrolled whether or not they had ventricular arrhythmias. Patients with no demonstrable arrhythmia probably would not benefit substantially from antiarrhythmic treatment. This subset of patients would tend to dilute any benefit of treatment in patients with ventricular arrhythmias.

The trials were too small. Only 1 involved >400 patients.[16] A properly designed prevention trial of antiarrhythmic drugs requires a total sample size of at least 1,000. The size is dependent on the mortality rate; that is, the higher the rate the smaller sample size needed.

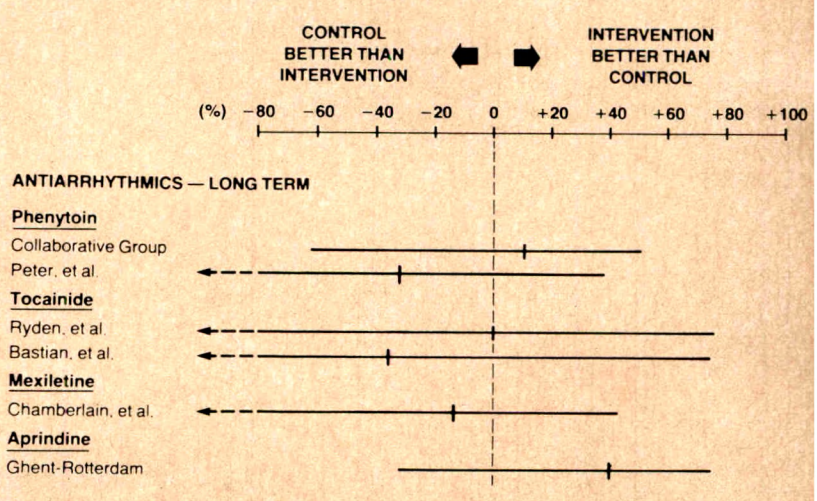

FIGURE 3. Estimates (**verticle bars on horizontal lines**) with approximate 95% confidence limits of the relative difference in total mortality between control and intervention in 6 long-term trials of antiarrhythmics of post–myocardial infarction patients.

The intervention programs in the reviewed trials were less than optimal. Nineteen of the trials used a fixed dose for each participant. In only 1 was the dosage adjusted based on arrhythmia suppression.[21,22] All trials evaluated a single drug. Thus, the programs are different from clinical practice, in which dosage is adjusted to achieve control of ventricular arrhythmias, and if 1 drug fails, many others are tested. It is not surprising that the effect of treatment on ventricular arrhythmias was moderate to uncertain in almost half of the trials that reported results on control of ventricular arrhythmias.

Adverse effects of treatment were very common and often led to treatment withdrawal. In the 13 trials of oral drugs (excluding the 7 lidocaine studies), about one fourth of the patients were not taking active oral treatment at the end of the trial.

All these factors indicate that the effect of antiarrhythmic drugs has not been fairly tested. Better attention should be given to certain features of study design. The trials should be limited to patients with known ventricular arrhythmias. Larger numbers of patients need to be studied. The objective of the trial should, as much as possible, mimic good clinical practice and examine whether arrhythmia control has a life-prolonging effect. For example, a patient who does not respond to a first (modest) dose of a drug ought to receive a higher dose and, if this is not effective, a second drug.

Treatment of ventricular arrhythmias helps some patients but harms others: Recent evidence suggests that antiarrhythmics may induce or worsen existing ventricular arrhythmias in 10 to 15% of patients.[23] This might be even more frequent in patients who receive digitalis or diuretics or both.[24,25] This explanation is difficult to prove. However, in future trials, special attention should be given to drug-induced arrhythmias, and the use of digitalis and diuretics should be closely monitored.

Conclusion: The first explanation—ineffectiveness of the drugs—appears to be the least likely. The second appears the most plausible, as all reviewed trials had severe limitations. The third explanation is difficult to reject until we know more about the intrinsic arrhythmogenic property of antiarrhythmics. Increased attention to methodologic issues will be necessary in future trials. Only then will it be possible to determine whether antiarrhythmic drugs exert a preventive effect on mortality.

Methods for Documenting Antiarrhythmic Efficacy

DONALD C. HARRISON, MD

Methods of documenting the efficacy of antiarrhythmic drugs are controversial because of wide inter- and intrasubject variability of the arrhythmias treated. In patients with symptomatic arrhythmias, clinical benefit can be inferred when symptoms are reduced or abolished, but the response cannot be quantitated. Multiple ambulatory monitoring periods before and during treatment permit determination of reductions of arrhythmia to levels of statistical significance but are costly and time-consuming.

Programmed electrophysiologic induction study may be helpful in determining efficacy of some antiarrhythmic agents because of its high specificity, but its use is limited because of a low sensitivity. Titrating patients with multiple dosing into accepted plasma level therapeutic ranges may be helpful for individual patient care but does not allow quantitation. Recently, a statistical model based on linear regression analysis with established 95 and 99% confidence intervals has been used to compare efficacy of quinidine and encainide with success. Wider application of this model is suggested for determining antiarrhythmic drug efficacy.

(Am J Cardiol 1983;52:37C–40C)

Clinical studies to establish therapeutic efficacy and to determine the relation between plasma concentrations of antiarrhythmic drug and effect are often performed in small groups of patients, frequently with inadequately designed studies. Therefore, questions remain about the basic approach for documenting individual and group antiarrhythmic efficacy for this class of agents.[1] Thus, the question of study type and design for demonstrating efficacy continues to be a major problem for the cardiologist/investigator.

A major problem results from spontaneous variation in the occurrence of individual ventricular premature complexes (VPCs) and of the more complex forms such as runs, couplets, bigeminy, trigeminy and the R-on-T phenomenon. Studies by Winkle[2] and Morganroth et al[3] demonstrated the wide range of variability for the occurrence of simple and complex VPCs in patients with heart disease. These investigators proposed methods that utilize multiple ambulatory monitoring periods that can provide data to document the efficacy of antiarrhythmic drugs. Other problems result from the use of electrophysiologic studies inducing recurrent ventricular tachycardia (VT) and determining which antiarrhythmic drug prevents such induction. As increasing sophistication and complexity of electrophysiologic study have been proposed to document the efficacy of drugs when administered for long periods, its use for the short-term evaluations of new antiarrhythmic drugs has become more limited.[4–6] Moreover, blood levels for the effectiveness of antiarrhythmic drugs and therapeutic indexes have been established by careful in-hospital control studies and carefully defined patient groups for some agents, but have not been evaluated as methods for establishing efficacy in ambulatory outpatients.[7–9] Other approaches using new biostatistical methods of linear regression analyses with the establishment of confidence intervals for homogenous patient groups have also been presented as means for determining the antiarrhythmic efficacy of a given drug.[10] These approaches have been criticized because they cannot be generalized to nonhomogenous patient groups nor to those who were not participants in developing the linear regression analysis as opposed to group responses.

Therefore, this report outlines the present state of knowledge with each of these approaches and provides the clinical investigator with a rationale for choosing 1 approach rather than another when confronted with studies relating to the use of a new antiarrhythmic agent. Considerable controversy has been expressed for each approach by specific proponents of an alternate approach during the past several years. An attempt is made to put each of these methods into clinical perspective.

Symptomatic Arrhythmias

For arrhythmias that present with clear-cut symptoms, such as syncope, hypotension and the appearance of symptomatically troublesome ectopic beats noted by

From Stanford University School of Medicine, Cardiology Division, Stanford, California.

the patient, it seems likely that drugs that alleviate these symptoms or markedly reduce them might be judged as effective. This may be true for patients who are good observers or the ones who have severe, highly symptomatic, life-threatening, recurrent VT. However, symptomatic arrhythmias occur in only a small group of such patients on a regular basis. The symptoms frequently do not correspond to periods in which objective documentation of the arrhythmia has occurred, and few patients are good observers. This approach will not lend itself to objectivity and a likelihood of demonstrating efficacy to a regulatory agency. For this reason such approaches have not been taken by most investigators who attempt to document the effectiveness of antiarrhythmic drugs during the past decade.

Use of Ambulatory Arrhythmia Monitoring

With the advent of 24-hour ambulatory monitoring, it became exceedingly easy to document that many patients have ectopic VPCs.[1] These have been documented with various degrees of frequency and varying degrees of complexity in patients with heart disease.[11] Clearly, by establishing entry criteria, one can choose patients to enter major drug protocols who have a high level of ventricular arrhythmia. However, because of marked spontaneous variability,[2,3] the degree to which suppression of such arrhythmias must be documented with the administration of antiarrhythmic drugs makes these techniques for the study of drugs difficult. They frequently lead to high levels of ≥60 VPCs required for entry into a study. Depending on the number of pretreatment recordings and the number of recordings once the patient is receiving established antiarrhythmic drug therapy at steady-state levels of the compound, varying degrees of reduction in VPCs are required for documenting efficacy.[2,3] In general, with 2 recordings before and 2 recordings during treatment, a 75% reduction is considered to be significant. Many drugs, such as beta-blockers and some of the class I antiarrhythmic drugs, do not reduce arrhythmias more than this; therefore, their documentation using ambulatory monitoring is difficult.

In addition, these approaches are costly and, because they require establishing a threshold for entering into a study, most patients will have high levels of ventricular ectopic activity or be in a period in which they are in the peak of their cycle for spontaneous variability. The patients at the nadir of their spontaneous variability are unfortunately excluded from study when they do not achieve the threshold and later may have a much greater frequency of ectopic rhythms and complexity. Using these techniques for a threshold determination before entry will bias most studies into showing efficacy for an agent.

Although spontaneous variability of VPCs in individual patients makes determination of individual response and efficacy difficult, group responses can be used to assess efficacy over short time intervals.[2,12] When group data without treatment are compared for several different monitoring intervals separated by time, there is a remarkable comparability of the number and frequency of VPCs for the groups.[12] Thus, reduction in the average VPCs in such a patient group can be used to judge antiarrhythmic efficacy.

Electrophysiologic Studies for Drug Efficacy

Program stimulation by electrophysiologic methods to produce a prototype arrhythmia that has been observed in a patient under spontaneous conditions has become a standard method of examining the efficacy of antiarrhythmic drugs. Such programs are discussed in greater detail in Ruskin's report in this present symposium. Although initially these techniques appeared promising,[4–6] several problems have arisen. First, such techniques require hospitalization and electrophysiologic study in a sophisticated laboratory. Because of their cost and risk to patients, they can be used in only those patients who have already experienced a life-threatening arrhythmia. For most investigators, this has required documentation of sustained VT or ventricular fibrillation (VF). Second, as attempts have been made to make electrophysiologic testing more specific, more complex and sophisticated protocols have been introduced. The use of 3 programmed premature stimuli and the use of intravenous infusions of catecholamines have helped to increase the specificity of the tests but have markedly limited their sensitivity for detecting the efficacy of an antiarrhythmic drug. A single drug frequently cannot be demonstrated to be efficacious against electrophysiologic induction in >15% of patients. Combined drugs may reach levels in the 30% range for efficacy. Electrophysiologic study with programmed stimulation to produce a prototype arrhythmia and then to determine which antiarrhythmic drug prevents the reinduction of the arrhythmia has been used to determine the efficacy with increasing frequency in the past 5 years.

In addition, a drug could be highly effective in preventing recurrences of life-threatening arrhythmias without preventing induction. This has been demonstrated for amiodarone, encainide and lorcainide.[13,14] Finally, I suggest that different end points other than preventive induction of VT might be considered for these tests. These studies are not helpful in many of the patients with less-than-life-threatening arrhythmias and are not generally used in these patients.

Blood Level Determinations for Therapeutic Effect

For several antiarrhythmic drugs, the therapeutic effective blood level has been well established in group studies.[7–9] New methods such as gas chromatography, high-pressure liquid chromatography, mass spectrometry and immunoassay for antiarrhythmic drugs have permitted their easy detection in plasma. Thus, it might be possible to establish therapeutic ranges for the efficacy of several of these drugs and simply use the observation that establishing a plasma level in patients within the therapeutic range might markedly reduce the occurrence of arrhythmias. Such studies fail to take into account the individual patient variability that has been noticed when the patients are under intense study in

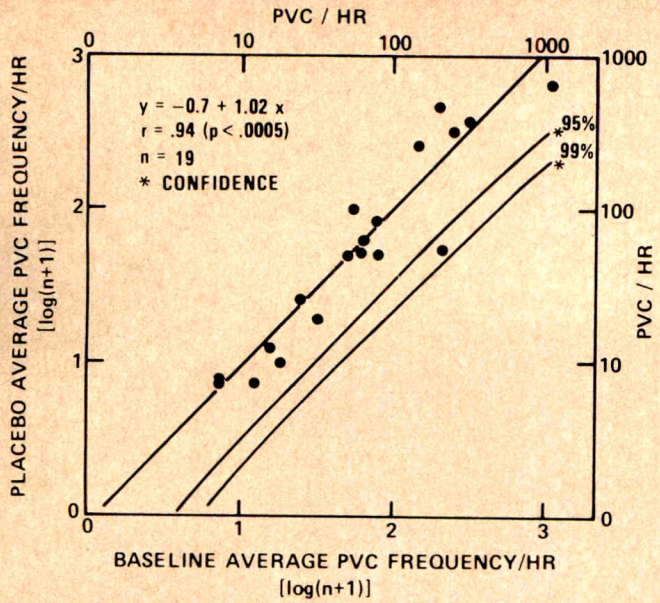

FIGURE 1. Demonstration of linear regression analysis with 95 and 99% confidence intervals of variability for baseline and placebo observations of the average frequency of premature ventricular complexes (PVCs) per hour of ambulatory electrocardiographic recordings. The analysis was performed on log (PVC frequency + 1) with corresponding absolute values on the opposite scale. The 95 and 99% confidence lines represent the 1-tailed confidence intervals for individual data points. Reproduced from Sami et al[10] with permission of the publisher.

clinical research units. Thus, this technique may not be helpful in determining individual patient responsiveness under different clinical conditions, especially in those in ambulatory outpatient settings.

Statistical Models Based on Linear Regression Analysis

To develop standards for distinguishing efficacy of antiarrhythmic drugs from spontaneous variability of VPCs, a new statistical approach was applied in 21 patients and was used to compare the response with 2 antiarrhythmic drugs by our group at Stanford.[10,15] Patients underwent ambulatory monitoring and exercise testing before and during 2 weeks of placebo therapy. A linear regression analysis was used to describe the relation between baseline and placebo VPC frequency and to set 95% and 99% 1-tailed confidence intervals for the relation (Fig. 1).[10]

The lower limits of baseline of VPC frequency for which this analysis could distinguish a placebo from true drug response was 2.2 VPCs/hour for ambulatory monitoring and 1.2 VPCs/min of exercise testing. To establish efficacy with 95% confidence, the minimal percent reduction of VPCs between baseline and placebo visits was 68% for treadmill testing and 65% for ambulatory monitoring.[10] The shortcomings of this technique are that new standards must be developed in homogenous patient groups to be studied with a particular agent, and that several ambulatory monitoring and treadmill sessions are required. Despite these problems, we believe the method has wide adaptability and should be further assessed.

Clinical Perspectives for Documenting the Effectiveness of Antiarrhythmic Drugs

When considering the various methods of documenting the effectiveness of antiarrhythmic drugs, several considerations for the clinician become apparent. Initially, it should be determined whether or not the approach is to demonstrate effectiveness in an individual patient or in a group of patients with a similar disease process. Based on these considerations, a rational approach can be developed.

For patients on an individual basis, 3 approaches seem relevant. First, for patients who have symptomatic ventricular arrhythmias either resulting in syncope or the detected presence of multiple VPCs, the abolition of symptoms with the administration of an antiarrhythmic drug in those patients who are careful observers appears to be a rational approach.

Second, when using multiple ambulatory monitorings before and after the administration of an antiarrhythmic drug, it seems feasible to use a 75% reduction in either complex forms or in the absolute frequency of VPCs as an endpoint for documenting the efficacy in a given patient. Whether or not reduction of this degree will reduce the prevalence of sudden death in this patient population has not been determined. Because only 1 episode of VF or sustained VT is necessary to result in death, it is problematic whether reductions of 75% in complex forms and in VPCs can be used as documenting efficacy in a given patient, particularly if death is the endpoint used and it occurs with a single episode of VF. This question can only be answered after further study.

Finally, an approach to administer the drug so that the patient's plasma concentration falls within a range that has been previously established by careful clinical investigation seems rational. Documenting that the peak and trough of the plasma concentration curve based on long-term administration all fall within the established therapeutic range for the given agent might be considered as establishing efficacy for a given patient. No studies have been successful in documenting this approach, although it was used to establish drug levels in the Beta-Blocker Heart Attack Trial[16] with a successful reduction in total and sudden cardiac deaths.

The approach to documenting antiarrhythmic drug efficacy in groups of patients with homogenous disease who have similar arrhythmias appears much more straightforward. By using ambulatory arrhythmia monitoring before and after administration of an antiarrhythmic drug, a rational approach should be possible. Patients in groups of 20 or more with homogenous disease processes have day-to-day variations in the average frequency of arrhythmias that are slight when averages for the group are utilized. Thus, a statistical reduction of even 25 or 30% in a group of patients should be sufficient to demonstrate that the drug has some degree of efficacy. It has been argued that reductions >70% in patients having ≥60 VPCs/min should be taken as clear-cut evidence of antiarrhythmic efficacy. The level of reduction of overall VPCs to document efficacy for such study protocols has not been defined and it seems

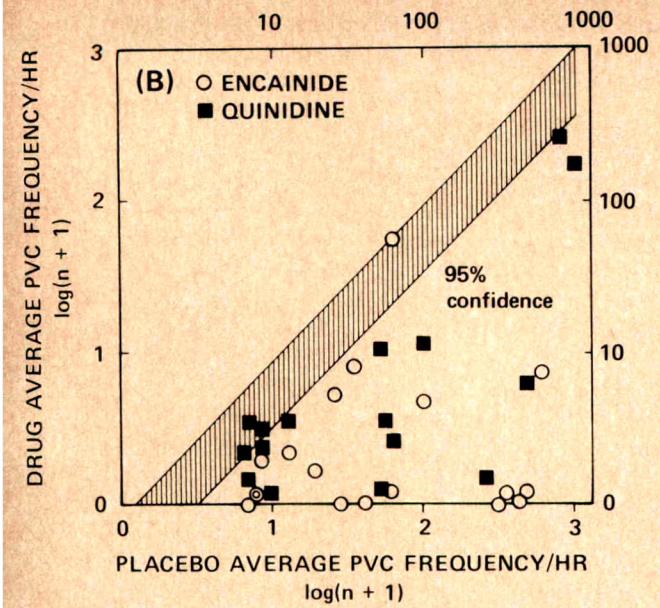

FIGURE 2. Responses of patients to encainide and quinidine. The shaded area represents the 95% confidence level from Figure 1. To distinguish true drug response from placebo effect at 0.05 level of significance, the single point that describes the placebo and postdrug responses must fall below the 95% confidence limit. The higher the average frequency of premature ventricular complexes (PVCs) during placebo therapy, the lower the percent reduction required to establish drug efficacy at a given confidence interval. Reproduced from Sami et al[15] with permission of the publisher.

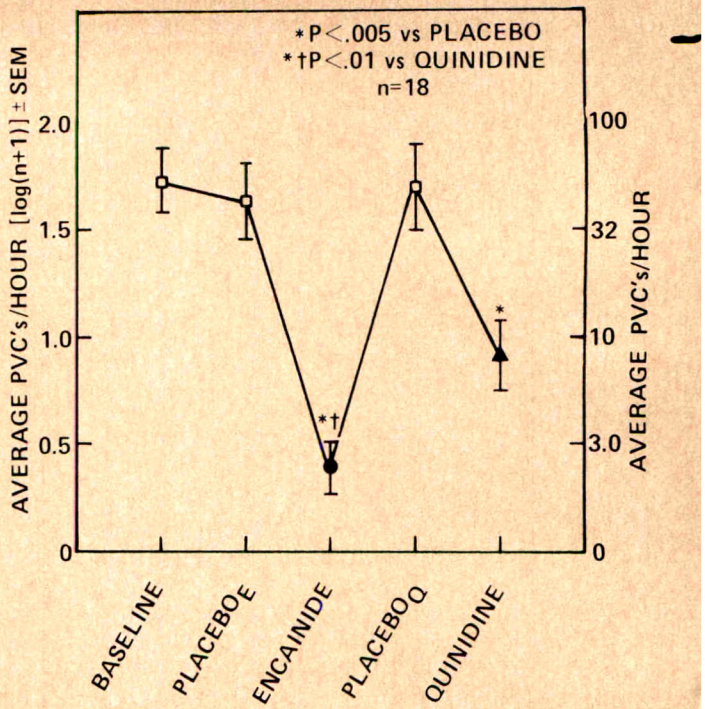

FIGURE 3. The means and standard errors of the mean for the average hourly frequency of premature ventricular complexes (PVCs) on ambulatory monitoring for each of 5 visits is shown. Paired *t* tests were used to compare the response to each drug with the prior placebo response and with the response to the other drug. Placebo$_E$ is that preceding encainide; placebo$_Q$ is that preceding quinidine. SEM = standard error of the mean. Reproduced from Sami et al[15] with permission of the publisher.

likely this reduction of total VPCs might not indicate whether or not sudden arrhythmic death would be reduced.

A much more rational approach, in my opinion, is the use of ambulatory monitoring twice before administering an antiarrhythmic drug and the establishment, by linear regression analyses, of the relation between a response with a placebo and with an entry ambulatory monitoring. Establishing by biostatistical means the 95 and 99% confidence intervals becomes possible. Thus, the administration of a drug to a group of patients that falls within such a homogenous disease process can demonstrate efficacy.[10,15] Such approaches have been documented with encainide and quinidine in our laboratories (Fig. 2 and 3). It has also been possible to establish that encainide is more effective than quinidine in reducing such arrhythmias both during ambulatory monitoring and in exercise testing.[15] This approach has great promise for studying the efficacy of antiarrhythmic drugs in groups of patients with complex and frequent ectopic rhythms. This method should gain more widespread use for clinical research protocols in the future. Other new approaches that would have wide applicability should be sought.

Role of Electrophysiologic Techniques in the Selection of Antiarrhythmic Drug Regimens for Ventricular Arrhythmias

JEREMY N. RUSKIN, MD, MARK H. SCHOENFELD, MD, and HASAN GARAN, MD

Programmed electrical stimulation of the heart provides a useful new technique for guiding the selection of antiarrhythmic drug regimens in selected patients with ventricular tachycardia (VT) or ventricular fibrillation. The technique of programmed electrical stimulation has been applied successfully in patients with recurrent sustained VT, out-of-hospital ventricular fibrillation and unexplained syncope in the presence of structural heart disease. The complete suppression of VT induced by programmed electrical stimulation by a drug regimen is highly predictive of freedom from both recurrent VT and sudden death. In addition, this technique may hold promise as a means of assessing the arrhythmogenic effects of antiarrhythmic drugs in selected patients.

(Am J Cardiol 1983;52:41C–46C)

The use of programmed electrical stimulation of the heart in conjunction with intracardiac electrographic recordings has contributed importantly to our understanding of the mechanisms of ventricular tachyarrhythmias and has enhanced our ability to examine objectively the efficacy of therapeutic interventions in modifying or preventing their occurrence. In assessing the value of programmed stimulation techniques in the management of patients with ventricular arrhythmias, the following issues will be addressed: the sensitivity and specificity of tachycardias induced by programmed electrical stimulation, the safety and practicality of serial pharmacologic-electrophysiologic testing techniques, the reproducibility of responses to antiarrhythmic drugs during serial electrophysiologic testing, and the predictive value of programmed electrical stimulation in selecting long-term antiarrhythmic drug regimens.

Lown et al[1] proposed the hypothesis that the suppression of ventricular premature beats, particularly repetitive forms, serves as a reliable endpoint to guide the selection of drug regimens aimed at preventing life-threatening ventricular tachyarrhythmias. This approach relies upon the use of both ambulatory and exercise electrocardiography to assess patients' baseline arrhythmias without drugs, as well as responses during short- and long-term antiarrhythmic drug testing. The results of this approach in properly selected patients (such as in those with frequent spontaneous arrhythmias) are encouraging.[2] However, there exist important limitations to the use of ventricular ectopic activity as an endpoint for the selection of antiarrhythmic drug therapy in patients with life-threatening ventricular arrhythmias. Even complex forms of ventricular ectopic activity may be detected in patients at low risk for sudden death, raising significant questions about the specificity of this finding.[3–5] In some patients in whom ventricular ectopic activity does occur, marked variation in complexity and frequency of ventricular ectopic activity may be seen when the results of several monitoring periods are compared.[6–8] Such variability may, in some instances, be so great as to mimic a drug effect. Another problem arises from the fact that freedom from spontaneous ventricular ectopic activity seems not be a highly specific indicator of protection against ventricular tachycardia (VT) or ventricular fibrillation (VF). We have observed that 15 to 25% of patients resuscitated from an episode of VT or VF subsequently may be found to be free of significant ventricular ectopic activity during ambulatory monitoring. Therapy for such patients is impossible to evaluate using suppression of ventricular ectopic activity alone. In other studies, investigators have also demonstrated a potential for dissociation between the prevention of spontaneous or electrically inducible VT and the suppression of ventricular ectopic activity by both pharmacologic and nonpharmacologic therapy.[9,10]

These limitations led several groups to seek alternative and potentially more reliable measurements to

TABLE I Electrophysiologic Testing for Ventricular Arrhythmias—Massachusetts General Hospital Protocol

A. Withhold antiarrhythmic drugs (≥5 half-lives) under continuous electrocardiographic monitoring
B. Baseline electrophysiologic evaluation without antiarrhythmic drugs
   1. Sinus nodal function studies
   2. AV nodal and His-Purkinje system conduction times and refractory periods
   3. Programmed PVS to test for inducible VT or VF
      a. Single (V_1V_2) and double ($V_1V_2V_3$) PVS during NSR and RV pacing at 3 drive cycle lengths (600, 500 and 400 ms) from RV apex. If no VT or VF induced →
      b. Triple ($V_1V_2V_3V_4$) PVS during NSR and RV pacing* (3 drive cycle lengths) from RV apex. If no VT or VF induced →
      c. Repeat (a) and (b) from RV outflow tract
      d. Adjuncts (rarely used):
         1. Isoproterenol infusion
         2. Left ventricular stimulation
C. Serial electrophysiologic-pharmacologic testing to define suppressive antiarrhythmic drug regimen.

* Triple PVS during RV pacing employed only in patients with clinically-proven spontaneous VT or VF.

AV = atrioventricular; NSR = normal sinus rhythm; PVS = premature ventricular stimulation; RV = right ventricular; VF = ventricular fibrillation; VT = ventricular tachycardia.

guide the selection of antiarrhythmic drug therapy. Early studies indicated that VT comparable in rate and morphology to that observed clinically could be initiated reproducibly by programmed cardiac stimulation in a majority of patients with a history of sustained ventricular tachyarrhythmias. After these initial observations, it became apparent that the use of sequential drug trials in conjunction with programmed cardiac stimulation would allow responses to individual drugs to be analyzed readily and in a highly reproducible fashion, thus providing an objective basis for the selection of long-term antiarrhythmic drug regimens in individual patients.[11–29]

Methods

The methods of electrophysiologic study used in this laboratory are outlined in Table I. The endpoint of programmed cardiac stimulation is the reproducible initiation of either sustained or nonsustained VT in response to some portion of the stimulation protocol. If sustained VT is induced, extrastimuli or bursts of rapid ventricular pacing are applied to interrupt the arrhythmia; sustained arrhythmias that result in angina or loss of consciousness are terminated with immediate asynchronous external electrical countershock.

The performance of baseline electrophysiologic studies in the absence of antiarrhythmic agents provides a reliable and consistent standard by which the efficacy and adverse electrophysiologic effects of antiarrhythmic drugs may be objectively assessed. In addition, a subset of patients with a history of spontaneous VT or VF will have no inducible arrhythmia at initial testing in the absence of drugs.[30] Serial antiarrhythmic drug testing without the benefit of baseline electrophysiologic observations without drugs will mask such patients and may, in some instances, obscure the fact that an antiarrhythmic agent either precipitated or exacerbated their spontaneous arrhythmias. Furthermore, preliminary logistic regression analysis of patients with VT or VF studied in our laboratory reveals that the results of initial electrophysiologic studies in the absence of drugs is an important predictor of the degree to which subsequent serial testing will achieve suppression of an inducible arrhythmia. In our patients, 77 and 73% of patients in whom nonsustained VT or VF, respectively, were induced achieved complete suppression of inducible arrhythmia during serial drug testing, whereas only 53% of patients whose baseline study revealed inducible sustained VT achieved suppression during subsequent drug testing (unpublished observations).

Sensitivity and specificity of induced arrhythmias: Some investigators have considered the initiation of "repetitive ventricular responses" of <5 beats to be a sufficient endpoint by which to assess antiarrhythmic drug efficacy during programmed stimulation protocols.[31,32] A repetitive ventricular response was originally defined as ≥1 nonstimulated premature ventricular depolarizations occurring reproducibly in response to a single stimulated premature ventricular depolarization delivered during sinus rhythm or atrial pacing. Greene et al[31] reported the induction of a repetitive ventricular response in 44 of 50 patients (88%) with a history of recurrent VT and in none of 12 control patients, suggesting that the induction of a repetitive ventricular response was a sensitive indicator of ventricular electrical instability and that the acute suppression of repetitive ventricular responses by drugs was a useful indicator of long-term antiarrhythmic efficacy. However, Ruskin,[33] Mason,[34] and their co-workers observed only a 15% incidence of repetitive ventricular responses in response to programmed single ventricular extrastimuli during sinus rhythm and atrial pacing in patients with recurrent VT or VF. This latter work indicated that repetitive ventricular responses induced in response to single ventricular extrastimuli during sinus rhythm or atrial pacing were an insensitive index of susceptibility to ventricular arrhythmias in patients with a history of life-threatening arrhythmias. In a later study by Farshidi et al,[35] repetitive ventricular responses that occurred after ventricular premature stimulation delivered during a paced ventricular drive had sensitivity and a specificity of 91%. Nacarelli et al[36] also determined that in patients with spontaneous VT, the induction of repetitive ventricular responses during ventricular pacing was more sensitive, although far less specific, than repetitive ventricular responses elicited during atrial pacing. Although a large prospective study by Livelli et al[37] using paced ventricular drives also found that the repetitive ventricular response had high sensitivity (92%), there was low specificity (57%) for detecting patients with previously documented spontaneous VT. Thus, the induction of a repetitive ventricular response is not a useful endpoint for defining antiarrhythmic therapy for patients with a history of ventricular tachyarrhythmias because of its low sensitivity when elicited during sinus rhythm or atrial pacing and its low specificity when elicited during ventricular pacing. In contrast, VT can be initiated by programmed cardiac stimulation in approximately 90% of patients with clinically documented, recurrent sustained VT related to coronary artery disease.[37,38] Furthermore, the specificity of VT initiated during programmed ventricular stimulation is extremely high, approaching 99% in the studies reported to date.[37,38] The sensitivity of programmed cardiac stimulation in patients with a clinical history of recurrent, nonsustained VT is somewhat lower, about 60%.[37,38] In patients with a clinical history of out-of-hospital VF we have found that VT or VF can be initiated reproducibly in approximately 75%.[22,39]

Serial drug testing: After a baseline study without drugs has been completed, antiarrhythmic agents are tested serially in selected patients for their ability to prevent initiation of VT by programmed cardiac stimulation. Standardization of electrophysiologic techniques and serial drug testing protocols

from one laboratory to another is presently lacking, rendering the interpretation and comparison of results of electrophysiologic-pharmacologic testing trials extremely difficult. In particular, some laboratories administer several parenteral agents in succession during the course of a day's testing, allowing for the accumulation of multiple antiarrhythmic drugs without adequate time for washout. Potential drug interactions may confound the findings at the time of electrophysiologic study in these patients and exclude a useful agent from consideration. For this reason, some centers, including our own, undertake serial testing only when steady-state serum drug concentrations have been achieved during long-term oral therapy and only after adequate washout of any previously administered antiarrhythmic drug has occurred.

Electrophysiologic testing of a drug during long-term oral therapy may be preferable to testing after the short-term intravenous administration of an antiarrhythmic agent. Variations in absorption and metabolism may contribute to electrophysiologic differences between testing after an intravenous loading dose and chronic oral therapy with the same agent.[40,41] Active metabolites of a number of drugs, including aprindine, lorcainide, procainamide, propranolol, verapamil and encainide, have been described, each of which may contribute to an agent's antiarrhythmic (or arrhythmogenic) potential. The clinical electrophysiologic effects of a drug are therefore better determined after several dosing intervals rather than a single intravenous loading dose or infusion. In addition, blood levels soon after intravenous loading may not reflect myocardial tissue levels. This is especially true of propranolol and quinidine, which concentrate in the myocardium after some delay.[40] Another advantage of studying patients while they are receiving a drug orally is that many of the potential side effects associated with a particular drug will be better and earlier appreciated.

The endpoint of serial drug testing is the complete suppression of inducible VT or VF by an antiarrhythmic drug. In a substantial percentage of patients, however, the goal of complete suppression of inducible arrhythmia cannot be achieved. Several investigators have commented on the ability of some antiarrhythmic agents to slow the rate of induced tachycardia, thereby rendering the patient less symptomatic during the arrhythmia and possibly allowing for the addition of pacemaker therapy to more effectively control recurrent tachycardias.[13,15,24,42,43] However, the efficacy of this approach has not been conclusively demonstrated. In addition, antiarrhythmic therapy may render a tachycardia more difficult to induce by programmed cardiac stimulation, requiring more aggressive modes of stimulation for initiation. The latter alteration may be predictive of the absence of recurrent spontaneous VT during long-term follow-up in patients in whom complete suppression cannot be achieved.[44]

We have observed that most antiarrhythmic drugs have an efficacy rate of about 25% during serial testing in patients with ventricular arrhythmias. Swerdlow et al[45,46] found that single agents averaged <15% efficacy, although these investigators used a more aggressive stimulation protocol. In addition, there was no statistically significant difference evident when the efficacy of various single agents was compared in their study.

Where single drugs are not effective in preventing the initiation of VT by programmed cardiac stimulation, a combination of drugs may be required. In our experience, 33% of patients have been discharged with at least 2 drugs after serial electrophysiologic testing, and 5% received 3 drugs. Caution is, however, recommended when combining 2 type I antiarrhythmic agents when neither drug alone has been successful in preventing the initiation of VT or VF. In 1 study, although induced VT was slower and better tolerated with a combination of 2 type I agents, in no case was the initiation of sustained VT prevented.[47] In our experience, the combination of a type IA drug such as quinidine with a type IB drug such as mexiletine has sometimes been effective when neither drug alone has effectively suppressed VT.

Adverse electrophysiologic effects of antiarrhythmic drugs: Antiarrhythmic drugs may exert a variety of unfavorable electrophysiologic effects in patients with ventricular arrhythmias. These effects include facilitation of induction of an arrhythmia, acceleration of the tachycardia rate, conversion of nonsustained to sustained VT or VF, and induction of nonclinical forms of VT. These adverse effects are observed frequently in the electrophysiology laboratory during serial antiarrhythmic drug testing. The precise clinical relevance of these effects has not been defined. We have found that some patients have both spontaneous and inducible VT in the presence of an antiarrhythmic drug and have no evidence of inducible VT in the absence of that drug.[22] In this subgroup of patients, we discontinue antiarrhythmic drug therapy and have observed no recurrent arrhythmias in any patient in whom electrical initiation of the arrhythmia could be achieved only in the presence of antiarrhythmic drugs.

Results of Electrophysiologic-Pharmacologic Testing

Of 262 patients with a history of spontaneous VT studied at our institution, 190 (73%) had inducible VT at the time of initial electrophysiologic evaluation. Multiple logistic regression analysis in this series of patients demonstrates that the most potent predictors of inducibility, in decreasing order of importance, are the presenting arrhythmia, a history of myocardial infarction, and previous number of empiric drug trials (unpublished observations). Of the patients who present with a history of sustained VT, 90% had inducible VT during electrophysiologic studies, compared with 57 and 66% of patients presenting with nonsustained VT and VF, respectively ($p < 0.001$).

For patients with inducible arrhythmias, early studies indicated a high (60 to 70%) success rate in defining an effective antiarrhythmic regimen by serial drug testing.[14,15] More recently, Swerdlow et al[46] defined effective regimens for only 32% of their patients during serial drug testing; this may reflect a more aggressive stimulation protocol than that used in earlier studies.[48] We have used serial drug testing to evaluate 173 patients with spontaneously occurring VT or VF who were found to have inducible arrhythmias at the time of the initial electrophysiologic studies and, thereby, defined therapy that resulted in complete suppression of inducible VT and VF in 118 cases (68%). Stepwise multiple logistic regression analysis was applied to a variety of clinical variables to determine the predictors of a successful response to antiarrhythmic therapy during serial testing. The major determinants of a successful outcome (such as suppression of an inducible arrhythmia) during serial drug testing were, in decreasing order of importance, the number of previous drug trials, the induced arrhythmia (induced sustained VT was harder to suppress than induced nonsustained VT or VF), and the presenting (spontaneous) arrhythmia (unpublished observations). Patients who present with sustained VT

were harder to treat (54% suppression) than those with nonsustained VT (76% suppression) or VF (80% suppression) ($p < 0.001$). This contrasts with the report of Swerdlow et al,[49] who found that the efficacy of acute antiarrhythmic drug trials was predicted by fewer coronary arteries with ≤70% stenosis, female sex, and fewer episodes of arrhythmia. Spielman et al[50] found that by univariate analysis the following 4 factors were associated with successful medical treatment: age <45 years, left ventricular ejection fraction >50%, hypokinesia as the only contraction abnormality and the absence of organic heart disease. Rosen et al[51] examined 41 patients with inducible sustained VT and evaluated the ability of serial drug testing to render VT noninducible or nonsustained ("drug responders"). Logistic regression analysis by these workers demonstrated no independent contribution to outcome by the patient's sex, presence of coronary disease, or cardiomegaly, but the number of empiric drug trials before the electrophysiologic studies was a significant (inversely correlated) independent predictor of outcome. Some, if not all, of these differences may be a result of differences in the stimulation protocols, definitions of a favorable response, antiarrhythmic drugs tested and composition of the patient populations.

Reproducibility of electrophysiologic responses to drugs: The reproducibility of responses to an antiarrhythmic drug during serial electrophysiologic testing is high.[52] We studied 65 patients in whom complete suppression of an inducible arrhythmia (VT or VF) was achieved during serial drug testing. In these 65 patients, repeat programmed ventricular stimulation was performed with precisely the same drug regimen 1 to 5 days later. No attempt was made to control for the time of day at which these studies were performed. Sixty-one of 65 patients (94%) had concordant responses to programmed ventricular stimulation at the time of the second electrophysiologic test with the same antiarrhythmic drug regimen. In 4 patients (6%), discordant responses were observed at the time of the second electrophysiologic test. The presence of inducible VT at the time of the second test in these 4 patients remains unexplained and was not due to significant variations in plasma drug concentrations or a change in the site or mode of ventricular stimulation.

Predictive value of electrophysiologic-pharmacologic testing: Several studies have examined the positive predictive value of electrophysiologic testing in patients with recurrent, life-threatening ventricular tachyarrhythmias. In studies involving several hundred patients, the positive predictive value, defined as the percentage of patients in whom complete arrhythmia suppression is achieved during electrophysiologic testing and in whom no spontaneous arrhythmia occurs at 1 to 2 years of follow-up study, is 90 to 95%.[20,23,39,53,54] The recurrence rate of VT in patients who are discharged from the hospital with a drug regimen on which VT is persistently inducible is 40 to 85% in the series reported to date. Thus, the positive predictive value of electrophysiologic testing (that is, suppression of an inducible arrhythmia predicting a successful outcome) is higher than the negative predictive value (that is, failure to suppress an inducible arrhythmia predicting spontaneous recurrence of the arrhythmia). Swerdlow et al,[53] in a study of 233 patients with sustained VT or VF, showed that in patients with a history of life-threatening ventricular arrhythmias, the 2 most important predictors of freedom from sudden cardiac death are the degree of congestive heart failure as defined by the New York Heart Association classification and the presence of an effective antiarrhythmic drug regimen as defined by electrophysiologic testing. These 2 variables were both powerful and independent predictors of survival in this patient population.[53]

TABLE II Selection of Techniques for Guiding Antiarrhythmic Therapy

Clinical features favoring the use of invasive electrophysiologic techniques:
Recent out-of-hospital cardiac arrest unassociated with acute myocardial infarction
Recurrent episodes of sustained VT with weeks to months between episodes
Infrequent episodes of symptomatic nonsustained VT
Recurrent, unexplained syncope with associated structural heart disease
Clinical features favoring the use of noninvasive monitoring techniques:
Frequently recurring (minutes to hours) sustained VT or VF
Frequently recurring symptomatic nonsustained VT
Exercise-induced VT

VF = ventricular fibrillation; VT = ventricular tachycardia.

Selection of patients for electrophysiologic testing: Electrophysiologic testing is an approach best applied to a specific set of clinical situations. Factors that influence the selection of electrophysiologic versus noninvasive techniques for guiding antiarrhythmic drug therapy are listed in Table II. The role of serial electrophysiologic studies in the treatment of patients with recurrent nonsustained VT is less clear. Empiric therapy using ambulatory electrocardiographic monitoring or exercise stress testing may be more useful when such episodes are frequent. When this is not the case, particularly if the nonsustained VT is rapid, disorganized, and associated with clinical symptoms, serial electrophysiologic studies may be useful in selecting antiarrhythmic therapy insofar as this form of VT may, in some patients, represent a prefibrillatory rhythm associated with a significant risk of sudden death.[55] Although the suppression of induced arrhythmia may afford protection against recurrence in many patients with recurrent nonsustained VT, the precise role of serial electrophysiologic studies in this group of patients is controversial and requires further study.[56,57]

Electrophysiologic evaluation with serial drug testing has also been applied successfully in the management of patients with previous out-of-hospital cardiac arrest. We evaluated electrophysiologic findings in 97 patients who survived an episode of out-of-hospital cardiac arrest unassociated with acute myocardial infarction.[22,39,58] Of the 97 patients, 73 (75%) had inducible VT or VF during programmed cardiac stimulation.

Complete suppression of electrically inducible VT was achieved in 55 of 69 patients who underwent serial antiarrhythmic drug testing or postoperative electrophysiologic evaluation or both; of these 55 patients, 4 (7%) died suddenly during a mean follow-up period of 22 months. Fourteen of the 69 patients still had electrically inducible VT despite pharmacologic, surgical interventions or both; 5 of these patients (36%) had recurrent cardiac arrest or sudden death during the follow-up period. Similar results have been reported by other investigators.[59,60] Thus, programmed cardiac stimulation identifies survivors of prehospital cardiac arrest who require antiarrhythmic therapy and predicts the efficacy of drug regimens and surgery in preventing subsequent recurrence.

Intracardiac electrophysiologic techniques have also been applied to the evaluation of patients with recurrent syncope of unknown origin.[61–64] Suppression of inducible arrhythmias by serial drug evaluation in these patients has been highly predictive of freedom from subsequent recurrent syncope, with a positive predictive accuracy of approximately 85%. However, the sensitivity of electrophysiologic testing techniques in detecting abnormalities in patients with unexplained syncope is far higher in the presence of underlying structural heart disease. Therefore, we recommend electrophysiologic testing in patients with recurrent unexplained syncope only if structural heart disease is present.

Complications of electrophysiologic procedures: DiMarco et al[65] recently reported on the complications associated with programmed cardiac stimulation at this institution. Complications were observed in 20 of 359 patients who underwent programmed electrical stimulation during 1,062 electrophysiologic procedures and included thromboembolism (9 patients), local or systemic infections (6 patients), and pneumothorax (5 patients). The morbidity rate corrected for the total number of separate procedures was 1.9%, and all 20 patients recovered from their complications without long-term sequelae. No procedure-related deaths were observed. On 105 occasions, a sustained ventricular arrhythmia was initiated that could not be interrupted with bursts of rapid ventricular pacing. All 105 of these episodes were terminated successfully by direct-current countershock without need for closed-chest massage or assisted ventilation. Thus, cardiac electrophysiologic procedures are safe when performed by experienced personnel in an appropriately equipped and staffed laboratory. The complications observed during these procedures relate to intravascular catheterization rather than the induction of potentially life-threatening arrhythmias.

Practical Implications

The induction of VT during programmed cardiac stimulation is a highly reproducible, sensitive and specific response in patients with a history of spontaneous sustained ventricular tachyarrhythmias. Furthermore, the complete suppression of inducible VT by an antiarrhythmic drug regimen is highly predictive of freedom from both recurrent arrhythmias and sudden death. As a result, serial electrophysiologic-pharmacologic testing is an extremely useful tool in the selection of antiarrhythmic drug regimens, particularly in patients with life-threatening ventricular tachyarrhythmias.

Many questions remain regarding the use of electrophysiologic techniques in the management of tachycardias. Standardization of nomenclature is lacking. Intracardiac stimulation protocols differ greatly among many laboratories, thereby contributing to substantial variation in the sensitivity and specificity of the technique and making the interpretation and comparison of results difficult. Furthermore, it is unclear whether complete suppression of inducible VT is required to prevent recurrence of spontaneous arrhythmia in all patients or whether "partial" suppression by drugs (for example, a major change in the grade of stimulation required to initiate VT) may be sufficient in some patients. The duration of the predictive value of electrophysiologic testing is yet to be defined. In addition, the management of patients who have no inducible arrhythmias at the time of initial electrophysiologic evaluation remains to be defined. This group constitutes a large subset of patients who present with spontaneous tachyarrhythmias.[30] Finally, prospective comparisons of electrophysiologic techniques with antiarrhythmic therapy directed by ambulatory electrocardiographic monitoring and exercise stress testing in patients with different frequencies and degrees of spontaneous arrhythmias are warranted.

Definition of Benign Versus Malignant Ventricular Arrhythmias: Targets for Treatment

J. THOMAS BIGGER, Jr., MD

The most important characteristics of arrhythmias that determine the need for treatment are the prevalence and clinical significance of the ventricular arrhythmia. Ventricular arrhythmias occur more frequently with advancing age, severity of heart disease and ventricular hypertrophy. Malignant ventricular arrhythmias are of 3 forms: out-of-hospital ventricular fibrillation (VF), recurrent sustained ventricular tachycardia and torsades de pointes ventricular tachycardia in the long QT syndrome. Each condition has a high 1-year mortality rate. Potentially malignant ventricular arrhythmias are ventricular premature complexes (VPCs) of >10 per hour 10 to 16 days after acute infarction and repetitive VPCs. The most malignant arrhythmias occur with severely depressed ventricular function, but VPCs alone have independent prognostic significance. Benign ventricular arrhythmias occur in patients without known heart disease and do not require treatment. The exact effect of frequent and complex VPC in these patients needs further definition. **(Am J Cardiol 1983;52:47C–54C)**

An important and controversial question in antiarrhythmic therapy is: Which ventricular arrhythmias should be treated? Several factors determine decisions about treatment: the mortality force of the ventricular arrhythmias, the presence and perception of symptoms and the efficacy, safety and convenience of treatment. My purpose is to examine the rationale to categorize patients with arrhythmia into groups based on prognosis and to outline which patients should be treated.

A fundamental prerequisite for a rational decision about therapy is knowledge of the prevalence and significance of the ventricular arrhythmias. This knowledge is needed to plan strategies for detection and for treatment. Prevalence of ventricular arrhythmia determines the feasibility of screening programs. The significance of an arrhythmia is an important determinant of treatment. The more malignant a ventricular arrhythmia is, the more important it is to treat it. Benign but symptomatic ventricular arrhythmias also may require treatment to alleviate the annoyance or anxiety they produce.

From the Division of Cardiology, Department of Medicine, Columbia University, and The Arrhythmia Control Unit, the Columbia-Presbyterian Medical Center, New York, New York. This study was supported in part by Grants HL-22982, HL-12738, and HL-70204 from the National Heart, Lung, and Blood Institute, the National Institutes of Health, Bethesda, Maryland; by Grant RR-00645 from the Research Resources Administration, Bethesda, Maryland; by a Grant-in-Aid from the American Heart Association, Dallas, Texas; and by grants from the Winthrop and Chernow Foundations, New York, New York.

For malignant arrhythmias, the primary concern is for efficacy of treatment. Inconvenience and even significant safety risks are worth taking in order to control the most malignant ventricular arrhythmias, such as frequently recurring ventricular fibrillation (VF). For benign arrhythmias, safety is the paramount consideration. Often, the significance of the arrhythmia in terms of short- and long-term morbidity and mortality rates is unknown; this makes decisions about treatment empiric.

Symptoms and patient attitudes often play a critical role in modifying decisions that otherwise would be clear as to the significance of the arrhythmias and the attributes of the best available treatment.

Background Knowledge

Important general facts about ventricular arrhythmias are listed in Table I. Studies using 24-hour electrocardiographic (ECG) recordings show that ventricular arrhythmias are common even in young, normal persons who do not have heart disease.[1–3] The prevalence of ventricular arrhythmias increases with age in subjects without clinically evident heart disease.[4] Also, adjusted for age, the prevalence of ventricular arrhythmias is greater in persons with heart disease.[4] The main feature of heart disease that is associated with ventricular arrhythmias seems to be scarring of the ventricular walls. The broader and more confluent the scarring of the ventricles, the more likely that ventric-

TABLE I Characteristics of Ventricular Arrhythmias in Man

They are common
They increase with age
They increase with ventricular scarring
Infarction
Hypertrophy
Infection
They do not increase with coronary atherosclerosis per se
They can be precipitated/aggravated by exercise
Ischemia
Increased sympathetic activity
Increased heart rate
Electrocardiographically similar arrhythmias may have different causes and significance

ular arrhythmias will occur. There is evidence to suggest that in chronic coronary heart disease, larger scars judged by electrocardiographic Q-wave scores or by left ventricular (LV) ejection fraction (EF) are associated with a significantly greater chance of ventricular arrhythmias.[5–7] The same relation holds early after myocardial infarction.[8] There is strong experimental evidence that infarct size is very strongly related to the inducibility of sustained ventricular tachycardia (VT) with programmed ventricular stimulation and to the VF threshold.[9] The ventricular scarring associated with myocardial hypertrophy in systemic hypertension or valvular heart disease and the fibrosis that follows a variety of diffuse myocardial injuries, for example, viral myocarditis, also increase the likelihood of developing ventricular arrhythmias. The overwhelming importance of scarring in chronic coronary heart disease was shown by Califf et al;[5,6] the extent of coronary atherosclerosis has no significant association with ventricular arrhythmias after adjusting for the association between LVEF and ventricular arrhythmias.

Ventricular arrhythmias may be precipitated or aggravated by exercise.[10] Triggering of arrhythmias by exercise is an important feature to contend with in arrhythmia detection and management. The primary mechanisms of exercise enhancement of arrhythmias are ischemia, enhanced sympathetic activity and the increase in rate per se.

Finally, arrhythmias can appear similar in electrocardiographic recordings but, nevertheless, have different causes and significance. This fact leads to the conclusion that important collateral evidence must be examined before drawing conclusions about how to manage ventricular arrhythmias. I divide the ventricular arrhythmias into malignant, potentially malignant and benign, based on outcome.

Malignant Ventricular Arrhythmias

There are 3 frequently recognized malignant, that is, lethal, ventricular arrhythmias in man: out-of-hospital VF, recurrent sustained VT, and torsades de pointes VT in the long QT syndrome. Each condition has a high mortality rate.

Out-of-hospital cardiac arrest: Much of what we know about the important syndrome of out-of-hospital cardiac arrest comes from work done by community-based emergency medical programs.[11–15] First, coronary heart disease is the most common etiologic form of heart disease in the population that has out-of-hospital cardiac arrest. Cardiomyopathy and valvular heart disease are also well represented. Every series of out-of-hospital cardiac arrest has a small and puzzling group that has no apparent heart disease. Studies by Cobb et al[14,15] show that acute myocardial infarction is not a common cause of out-of-hospital cardiac arrest, especially in patients who are resuscitated and admitted to the hospital. However, significant coronary heart disease is common among the survivors of out-of-hospital cardiac arrest and advanced coronary atherosclerosis, previous myocardial infarction and poor LVEF are all common in this group.[14,15]

Studies to date suggest that the 2 most common causes of out-of-hospital cardiac arrest are ischemic VF and sustained VT that degenerates into VF. Studies by Goldstein et al[16] suggest that as many as half of the out-of-hospital cardiac arrests are caused by ischemic episodes. Many of these episodes result in instantaneous death and the victims are not resuscitated. About 70% of survivors respond to programmed ventricular stimulation with inducible sustained VT that may or may not degenerate into VF.[17–20] This suggests that a similar sequence of events may have occurred during the previous spontaneous cardiac arrest. Kehoe et al[19,20] have presented evidence to support the proposal that some of the noninducible patients had VF as a result of ischemic episodes. Almost all patients who have VT or VF induced during ventricular stimulation have evidence of a ventricular scar, usually from previous myocardial infarction. It is quite likely that studies of survivors of out-of-hospital cardiac arrests are biased, that is, the samples are enriched with scar-related VT or VF. This is because patients with VT are more likely to remain awake, even if symptomatic, during attacks. An extended period of consciousness during VT gives these patients a chance to summon help and to survive until help arrives. Intense myocardial ischemia is more likely to produce abrupt VF without preceding VT and allow the victim no opportunity to seek aid. The longer time from the initiating event to the loss of consciousness in patients with scar-related VT makes it likely that this group is overrepresented among survivors of out-of-hospital cardiac arrest.

Three therapeutic approaches have been proposed for survivors of out-of-hospital cardiac arrest: electrophysiologically guided medical or surgical treatment,[17–20] medical therapy guided by arrhythmias detected during 24-hour ECG recordings and exercise tests[10] and blood level control only.[21] Treatment of survivors of out-of-hospital cardiac arrests is mandatory because untreated patients have a recurrence rate of about 25 to 30% within the year.

Recurrent sustained ventricular tachycardia: Recurrent sustained VT has been the subject of intensive study during the past 5 years. The causes of heart diseases for this arrhythmia are similar to those in survivors of out-of-hospital cardiac arrests. Coronary heart disease and cardiomyopathy account for almost

90% of these patients, with about 75% having coronary heart disease.[22–24] Ventricular scar also plays a major role in the pathogenesis of this syndrome; almost all of the coronary heart disease group have had a previous myocardial infarction and many have had a ventricular aneurysm. Viewed from the perspective of acute myocardial infarction, recurrent sustained VT is a rare syndrome, occurring in the postinfarction year in about 1 to 3 of 1,000 patients. However, these patients accumulate in considerable numbers because myocardial infarction is so common and because these patients often survive multiple episodes of VT. Untreated, recurrent sustained VT has a recurrence or mortality rate of about 40% during a year of follow-up study. Therefore, treatment is imperative. Although there is 1 report of successful treatment of recurrent, sustained VT guided by Holter ECG recordings and exercise testing,[10] the accepted approach to the therapy for this condition is electrophysiologic because the method is sensitive and specific.[25] The recurrence rate is substantially lower for patients who have conversion from inducible to noninducible during electrophysiologic studies done with drug treatment.[26–28] Also, there is substantial success with map-guided arrhythmia surgery in the patients in whom VT remains inducible while receiving the drugs tested.[29] Amiodarone has significant long-term efficacy, although it apparently fails during electrophysiologic studies.[30] There has been no randomized comparison of amiodarone and surgery in patients who have failed with conventional and experimental type 1 antiarrhythmic drugs. Therefore, the better choice between these 2 treatments is not yet clear.

Torsades de pointes in the long QT syndrome: Torsades de pointes is a rapid polymorphic VT with unique ECG features: The polarity of the QRS complex repeatedly twists from upright to inverted and back.[31] This type of ECG appearance usually is associated with a prolonged QT interval. There are 2 congenital forms of the long QT syndrome: one has dominant inheritance and is associated with congenital deafness and one has recessive inheritance and has no association with deafness.[32] In addition, there is a so-called acquired form of the long QT syndrome that is usually caused by electrolyte abnormalities, such as hypokalemia or hypomagnesemia or drug toxicity (for example, quinidine or tricyclic antidepressants).[33] As suggested by its bizarre ECG appearance, torsades de pointes is an unstable form of VT and is likely to deteriorate into VF.

There is no doubt that torsades de pointes is a malignant arrhythmia that requires treatment. The approach to therapy of this condition is as unusual as the ECG appearance. Emergency treatment includes *avoidance* of type I antiarrhythmic drugs, use of ventricular pacing and, occasionally, infusion of catecholamines. Evaluation of therapy usually is accomplished by on-line, real-time ECG monitoring and later by 24-hour ECG recordings. Long-term drug treatment almost always includes beta-adrenergic blocking agents and occasionally phenytoin. Drug-resistant cases usually can be successfully treated by left stellate ganglionectomy.[33–35]

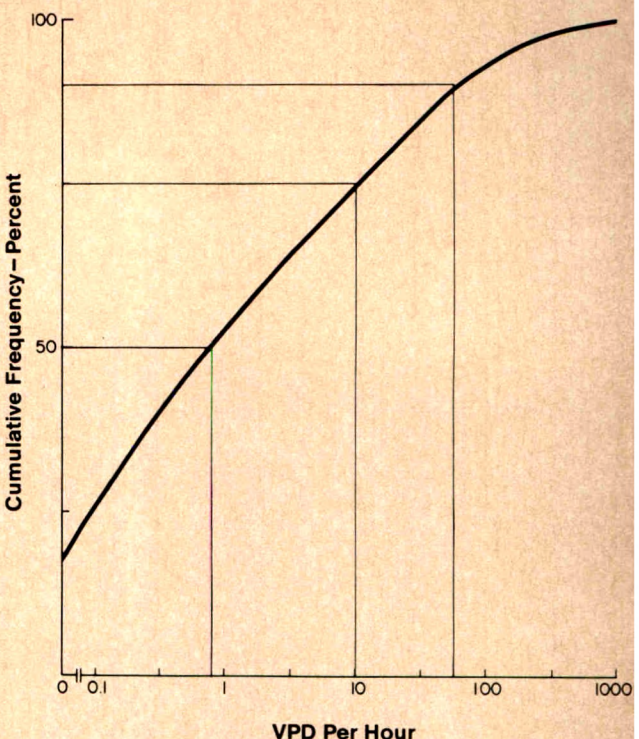

FIGURE 1. Cumulative frequency distribution of ventricular premature complexes (or depolarizations [VPDs]) expressed as the hourly average over 24-hours. The 50th percentile is just below 1 VPD/hour, the 75th percentile is at 10 VPDs/hour and the 90th percentile is at 60 VPDs/hour.

Potentially Malignant Ventricular Arrhythmias

The aforementioned arrhythmias classified as "malignant" were all examples of sustained ventricular activity. Studies performed over the past 10 years have identified several "potentially malignant" ventricular arrhythmias. These include frequent and repetitive but nonsustained ventricular premature complexes (VPCs) in patients with coronary heart disease, particularly those with previous myocardial infarction, and in patients with cardiomyopathy. Because the significance of ventricular arrhythmias in coronary heart disease and cardiomyopathy appears to be similar, these will be discussed together.

Frequent ventricular premature complexes: The prevalence and significance of ventricular arrhythmias in coronary heart disease have usually been studied after acute myocardial infarction. Most studies were done at about the time of patient discharge after an index myocardial infarction because this is a convenient time for both physician and patient and because of the high mortality rate 6 to 12 months after infarction.[36–39] The prevalence of VPCs 10 to 16 days after myocardial infarction is shown in Figure 1. Fifteen to 20% have no VPCs in a 24-hour recording, about 50% have an average of <1 per hour, 20 to 25% have ≥ 10 per hour, and only 5% have ≥ 100 per hour. The time between myocardial infarction and the 24-hour recording is an important determinant of VPC prevalence. If 24-hour recordings

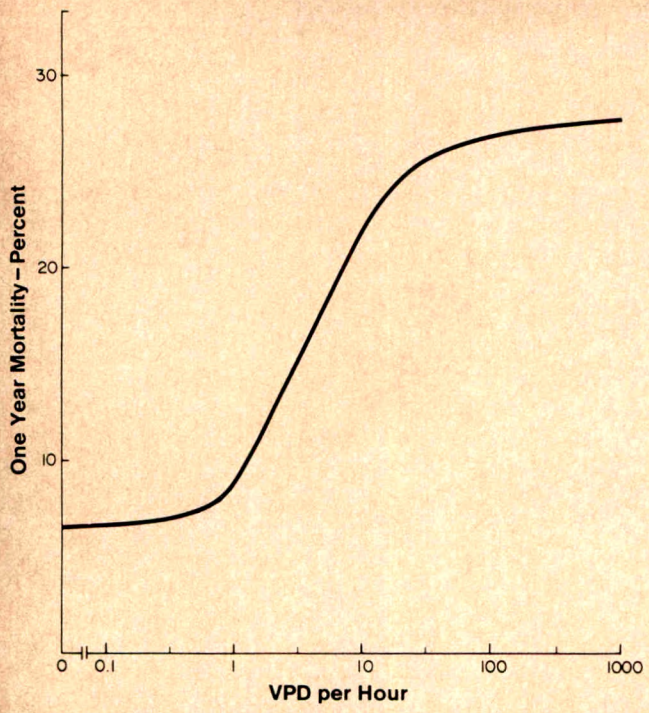

FIGURE 2. Mortality rate as a function of average hourly frequency of ventricular premature complexes (or depolarizations [VPDs]). Patients with <1 VPD/hour have a low mortality rate. The mortality rate increases sharply as a function of VPC frequency and reaches a plateau from 10 to 30 VPDs/hour.

are made at 3 to 5 days after infarction, any level of VPC frequency is less prevalent. Recordings made 6 to 12 weeks after infarction show a higher prevalence of frequent VPCs. The relation between the first-year postdischarge mortality rate and frequency of VPCs is shown in Figure 2. Interestingly, the relation is S-shaped. About half of the VPC-associated mortality rate increase is achieved at frequencies of 1 per hour and the mortality rate plateaus are at about 10 per hour. This means that the mortality rate is 20 to 25% for patients with ≥10 VPCs; patients with ≥100 per hour are at no greater risk than those with 10 to 100 per hour. As mentioned by Furberg elsewhere in this symposium, there has been no definitive trial to evaluate whether reducing the frequency of VPCs has a beneficial influence on postinfarction mortality rates. If one assumes that treatment can reduce mortality, one would reasonably conclude that patients with VPC frequencies >10 per hour should be treated; a cogent argument can be made for using an even lower frequency value as the criterion for treatment. The relation in Figure 2 calls into question the conventional frequency criteria for treatment of ventricular arrhythmias after infarction, usually 60 to 100 per hour or even more.

TABLE II Relation Between Repetitive Ventricular Premature Complexes and Mortality, Adjusted for the Effects of Frequency of Ventricular Premature Complexes

VPC Frequency (per hour)	Repetitive VPCs	Status		Total	Mortality	Odds Ratio
		Dead	Alive			
<10	Absent	31	349	380	8%	. . .
	Present	16	68	84	19%	2.7
≥10	Absent	6	36	42	14%	. . .
	Present	31	79	110	28%	2.2
	Total	84	532	616	14%	. . .

Chi-square total = 12.11, df = 2; chi-square interaction = 0.59, df = 1; chi-square association = 11.52, df = 1; summary odds ratio = 2.5.
VPC = ventricular premature complex.

Repetitive ventricular premature complexes: The complex feature of postinfarction VPC with the greatest significance is repetitiveness. Multiform VPCs have very little significance and R-on-T complexes have less prognostic significance.[38,39] About 25% of 24-hour predischarge ECG recordings contain repetitive VPCs; about 15% contain paired complexes only, and 10% contain both paired complexes and ≥1 episodes of nonsustained VPC runs (≥3 consecutive ventricular complexes at any rate). Recordings with runs but no pairs are extremely rare, only about 5% of the recordings with runs. The significance of repetitive VPCs in a Columbia University study is shown in Table II, adjusted for VPC frequency. Overall, the odds of dying are 2.5 times greater for patients who have repetitive VPCs compared with those who do not. Although there is a significant and moderately strong association between VPC frequency and repetitive VPCs, there is no interaction between these 2 factors with respect to mortality. The mortality rate for patients with VPC runs is sig-

TABLE III Ventricular Tachycardia Recorded Just Before Discharge From Hospital After Myocardial Infarction

Study	No. of Patients	Age Limit (yr)	1-Year Mortality	Duration of Recording (hours)	Ventricular Tachycardia	
					Definition of VT	No. With VT (%)
Anderson et al[40]	915	<66	4%	6	≥3 VPC >100/min	10 (1.1)
Bigger et al[41]	430	<76	13%	24	≥3 VPC Any rate	50 (11.6)
Kleiger et al[42]	289	<71	9%	10	≥3 VPC Any rate	10 (3.4)

VPC = ventricular premature complex. VT = ventricular tachycardia.

TABLE IV Nonsustained Ventricular Tachycardia After Infarction and Long-Term Mortality

Study	Patients (n)	Age	Follow-up (months)	Mortality (%) With VT	Mortality (%) Without VT
Anderson et al[40]	915	<66	48	25	13
Bigger et al[41]	430	<76	36	38	19
Kleiger et al[41]	289	<71	12	14	7

VT = ventricular tachycardia.

nificantly higher than for patients with pairs but no runs (chi-square association 11.52; $p < 0.001$). Adjusting for VPC frequency dichotomized at 10 per hour with the Mantel-Haenszel chi-square procedure or with logistic regression models, we found that repetitive VPCs add significantly and independently to the risk of dying. Table III is a summary of the 3 major studies of nonsustained VT in patients with recent myocardial infarction.[40–42] The prevalence of VT at the time of hospital discharge varies with age and base mortality rate, the recording duration, the sensitivity of the analysis method, and the definition of VT. If predischarge 24-hour recordings are done in a representative cross-sectional sample of the U.S. postinfarction population with a 10% 1-year mortality rate and then are analyzed by sensitive digital computer methods, the prevalence of VT is about 10%. The mortality influence of VT is large and remarkably constant across the 3 major studies (Table IV). In patients with runs, no relation has been found between the number of episodes of runs or the length of the runs and mortality in a year or more of follow-up (Fig. 3). However, the studies to date have been small and have not had much power to detect such relations should they exist. Nearly all episodes of VPC runs recorded predischarge are brief, infrequent, and asymptomatic.[40,41] Half of the patients have only 3 VPCs in the longest run and 30% have only a single run in the 24-hour recording. Considering these facts, it is remarkable that patients with runs have such a high mortality rate during follow-up study after infarction.

Relation of ventricular arrhythmias to left ventricular dysfunction: There are 2 hypotheses about the relation between ventricular arrhythmias and LV dysfunction: that ventricular arrhythmias contribute independent mortality force after adjusting for LV dysfunction, and that ventricular arrhythmias are strongly associated with LV dysfunction and that ventricular arrhythmias do not contribute independently to mortality after adjusting for LV dysfunction. Ruberman,[39] Moss,[37] and their co-workers analyzed for a relation between "complex" ventricular arrhythmias (bigeminy, multiform, pairs, runs or R on T) and postinfarction mortality rates, adjusting for LV dysfunction using the clinical diagnosis of heart failure. Both of these studies were large—1,739 and 940 patients, respectively; both used fairly brief ECG recordings, 1 hour and 6 hours, respectively; and both used clinical heart failure to adjust for LV dysfunction. Both analyses yielded a similar result: complex ventricular arrhythmias were significantly associated with follow-up mortality after adjusting for LV dysfunction. In a study of 395 coronary heart disease patients referred for cardiac catheterization, Califf et al[6] addressed the same question; only 53% of their patients had a previous myocardial infarction and most of these were in the remote past. Angiographic LVEF was used to adjust for LV dysfunction. A hierarchical scoring system using frequency, multiformity,

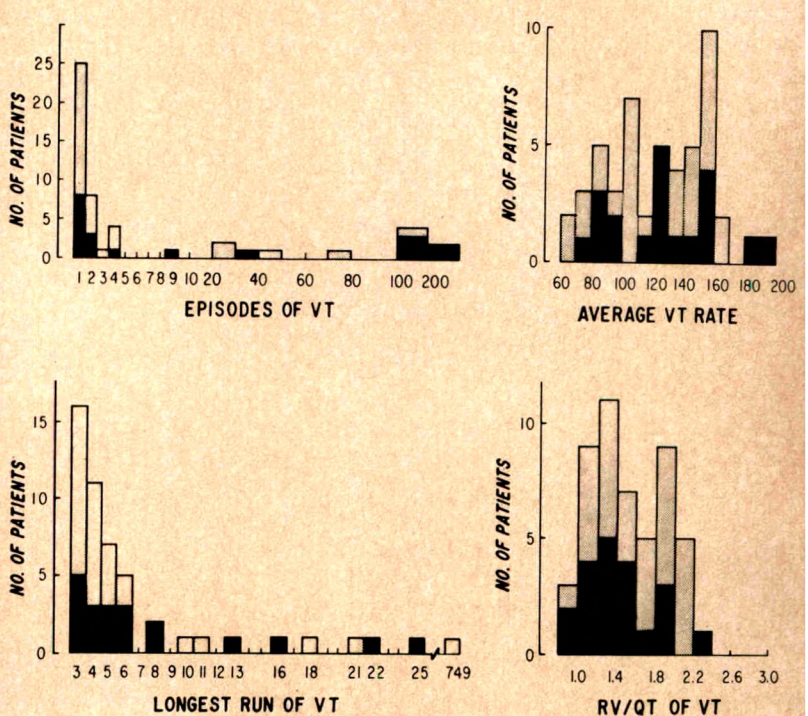

FIGURE 3. Characteristics of ventricular tachycardia (VT) 2 weeks after myocardial infarction in 50 patients. The **black portion** of the **bars** indicates the deaths. There is no indication that patients with more frequent, longer or faster episodes of VT have a higher death rate. However, this sample is too small to settle this question definitively. Reproduced from Bigger et al[41] with permission of the publisher.

TABLE V Mortality 1 Year After Infarction as a Function of Left Ventricular Ejection Fraction and Repetitive Ventricular Premature Complexes[43]

Ejection Fraction (%)	Repetitive VPCs	Status				Odds Ratio
		Dead	Alive	Total	Mortality	
>40	Absent	3	196	199	2%	...
	Present	4	51	55	7%	4.9
≤40	Absent	6	81	87	7%	...
	Present	12	35	47	25%	4.4
	Total	25	363	388	6%	...

Chi-square total = 14.37, df = 2; chi-square interaction = 0.27, df = 1; chi-square association = 14.10, df = 1; summary odds ratio = 4.8.
VPCs = ventricular premature complexes.

TABLE VI One-Year Mortality Rate in Patients With Inducible Ventricular Tachycardia/Ventricular Fibrillation After Myocardial Infarction[46]

Inducible VT/VF	Death in 1 Year		
	Present	Absent	Total
Present	10	28	38
Absent	7	120	127
Total	17	148	165

Mortality with VT/VF: 26%, mortality without VT/VF: 6%.
$p < 0.01$, odds ratio = 5.9.
VF = ventricular fibrillation; VT = ventricular tachycardia.

pairs and runs was used to grade the arrhythmias detected using a conventional Holter scanner to analyze 24-hour ECG recordings. However, after adjusting for LVEF, there was no significant independent relation between ventricular arrhythmias and mortality. However, when Califf et al used only clinical and noninvasive measures to adjust for LV dysfunction, they obtained a result similar to that of Ruberman and Moss. This analysis failed to eradicate the relation between ventricular arrhythmias and mortality. Thus, they concluded that the adjustment procedure of Ruberman and Moss failed because they used inadequate variables to represent LV dysfunction. Although the findings of Califf et al[6] were not obtained in patients with recent myocardial infarction, they nevertheless seriously challenge the conclusions of Ruberman[39] and Moss.[37] More recently, 2 studies have used radionuclide EF to adjust for LV dysfunction in postinfarction patients. The Multicenter Investigation of the Limitation of Infarct Size (MILIS)[43] reported findings in 388 patients (Table V) and the Multicenter Post Infarction Program (MPIP)[44] in 766 patients. Both of these studies used sensitive and specific computerized methods to analyze the 24-hour electrocardiograms and radionuclide methods to measure LVEF. In these preliminary analyses, MILIS used repetitive VPCs and MPIP used VPC frequency dichotomized at 10 per hour as arrhythmia endpoints. Both studies show that ventricular arrhythmias do contribute *independently* to the mortality risk in the year after myocardial infarction. This was an important point to settle because it forms a critical basis for treatment strategies aimed at reducing postinfarction death.

Our own working hypothesis is that ventricular arrhythmias are significantly and independently related to subsequent cardiac death in patients with coronary heart disease or cardiomyopathy. Also, we believe that certain patients with coronary heart disease and large scars have ventricles capable of supporting reentrant activity and VF even though these patients may not have significant ventricular arrhythmias in 24-hour ECG recordings. The subgroup with arrhythmogenic scars may be detected by programmed ventricular stimulation. Already there is some preliminary evidence for this hypothesis. Hamer,[45] Richards,[46] and their coworkers found that patients with recent myocardial infarction who have VT or VF in response to programmed ventricular stimulation have a 5- to 6-fold increased likelihood of having death or symptomatic arrhythmias in follow-up (Table VI). Hamer et al did a preliminary and superficial comparison of electrophysiologic studies and Holter recordings before the patients were discharged after myocardial infarction and found a rather poor correlation. So far, preliminary studies show very encouraging results, indicating that from among the group with large, confluent myocardial scars caused by infarction, programmed ventricular stimulation can be used to identify those who have the greatest potential for arrhythmic death. The relation between positive response to programmed ventricular stimulation early after myocardial infarction and spontaneous ventricular arrhythmias is not yet defined.

Benign Ventricular Arrhythmias

A number of studies have been done in apparently normal patients to determine the prevalence of ventricular arrhythmias and their significance. In a small study of 50 male medical students, Brodsky et al[1] found that 25 (50%) had some ventricular arrhythmia, but only 2% had >50 VPCs per 24 hours and only 4% had repetitive VPCs. Frequent and repetitive VPCs were found more often in Hinkle et al's[47] study of 301 apparently normal middle-aged men (median age 55 years) in a random population sample. To eliminate persons with asymptomatic coronary heart disease in their sample, Kostis et al[48] selected for study a group of 101 persons from 1,500 patients who were referred for coronary angiography. These 101 patients were normal as judged by physical examination, electrocardiography, chest roentgenography, echocardiography, exercise test, coronary angiography, and left ventriculography.[48] The group had a mean age of 49 years (range 16 to 68). The prevalence of VPC frequency was as follows: >1 per hour, 39%; >10 per hour, 20%; and >100 per hour, 4%. No repetitive forms were detected in any of the 101 patients and other complex forms were rare as well; multiform VPCs were found in only 4% and R and T in 2%. These findings are strikingly different from those of previous studies. The prevalence of VPC frequency in the Kostis sample is very similar to that found in patients with recent myocardial infarction. However,

the almost total lack of repetitive VPCs is the striking aspect of the study. This finding is in marked contrast to the findings in patients with heart disease[4] or in middle-aged men.[47] If validated, those findings indicate that the striking difference between normal and abnormal middle-aged persons is the prevalence of repetitive VPCs. Kennedy et al[49] asked the opposite question: whether or not frequent and complex ventricular ectopic activity indicates underlying coronary heart disease. From a group of 62 patients with ≥100 VPCs per hour and repetitive VPCs but normal 12-lead electrocardiogram, M-mode echocardiogram, and exercise test results, 25 were selected for coronary angiography. The primary indication for angiography was the presence of ventricular arrhythmias in association with coronary risk factors. The average age in the group was 47 years and the ventricular arrhythmias had been present for an average of 3 years. Coronary angiography showed significant coronary lesions in 25% (6 of 25) of the group. This study is very small and should be extended, but tends to support the view that most patients who have striking ventricular arrhythmias but normal noninvasive workup results do not have significant coronary heart disease.

Follow-up studies show that normal subjects who have frequent ventricular arrhythmias have an excellent life expectancy without antiarrhythmic drug treatment for follow-up periods of about 2 years. With the studies done so far, it is not possible to say that ventricular arrhythmias do not increase the risk of dying in normal persons compared with appropriate control groups. Given the mortality expectations for normal persons and assuming the same increment in risk attributable to VPCs as occurs in postinfarction populations (that is, relative risks of 2.0 to 3.0), a very large study would be required to detect such a difference. The sample size required would have to be well above 1,000 subjects. Nevertheless, one can say that the mortality rate in persons with apparently normal hearts and frequent ventricular arrhythmias is reasonably good. Given our current antiarrhythmic drugs, it is well not to treat these patients unless they are symptomatic or the arrhythmia demonstrates clear-cut malignant potential.

Treatment and Prophylaxis of Ventricular Arrhythmias in Acute Myocardial Infarction

RONALD W. F. CAMPBELL, FRCP, MB , ChB

Remarkable advances have been made in the management of cardiac disease in the last 20 years, but antiarrhythmic drug strategy in the acute phase of myocardial infarction remains less than satisfactory. Primary ventricular fibrillation (VF), once considered predictable on the basis of detection of "warning arrhythmias," cannot be anticipated. Management must be either expectant or prophylactic. Restriction of drug use to selected patients and the apparent lack of effect of VF on late prognosis argue for the former approach, yet safe and effective prevention of VF is an attractive therapeutic goal. High-dose intravenous lidocaine probably offers efficacy but the risk-benefit ratio of this regimen is still debated. Adoption of a prophylactic regimen mandates drug administration to a large number of patients who either are not at risk of developing VF (noninfarct patients) or who are destined not to develop VF (70 to 95% of infarct patients). Ventricular arrhythmias other than VF are common in acute infarction and, for emotional rather than scientific reasons, often are aggressively treated. Little evidence exists to support this management. Few ventricular arrhythmias at this time in infarction have either immediate importance or prognostic significance. Reevaluation of antiarrhythmic drug use and arrhythmia treatment in acute myocardial infarction is long overdue. However, there is a paucity of controlled data upon which to base new strategies, and clinical research in this field is hampered by ethical considerations, by rigidly held but unscientifically based beliefs and by a lack of fundamental knowledge of arrhythmia mechanisms and their significance.

(Am J Cardiol 1983;52:55C–59C)

Acute myocardial infarction (MI) is a dramatic clinical event associated with a high initial mortality rate. Ventricular fibrillation (VF) was identified as the major cause of death over 20 years ago but the association of ventricular arrhythmias and MI has been recognized for much longer. In 1586, Diversus provided a clear description when he wrote, "two signs indicate impending cardiac syncope and sudden death; first a sensation of sudden constriction of the heart . . . and second . . . an intermittent pulse." Since the establishment of coronary care units and the widespread availability of defibrillators, the emphasis of arrhythmia management has changed from the treatment of VF to the prediction and prevention of this arrhythmia. Yet, as more is understood of the natural history of MI and of the action of antiarrhythmic drugs, the optimal management of arrhythmias in early MI remains unclear.

The various strategies for antiarrhythmic drug administration that have been advocated and applied include selective use in patients with "warning arrhythmias," unselective prophylactic use in all patients with suspected acute MI, and use only in the treatment of VF and hemodynamically significant arrhythmias. In the United States, prophylactic lidocaine therapy is given to the majority of patients with suspected acute MI in an effort to prevent primary VF.

In Europe, where this policy is less common, greater reliance has been placed on speedy management of VF when it occurs or on selective prophylactic drug administration. No well-conducted comparisons of these various regimens have been made, largely because of the complexity of such an investigation and because of the large number of patients required. Moreover, VF occurring in hospital is rarely fatal, and it is unlikely that there is an important difference in hospital mortality rates related to methods of antiarrhythmic drug use. Less certain is whether the long-term mortality rate is influenced by short-term arrhythmia management.

Frequency of ventricular arrhythmias in acute myocardial infarction: After the onset of symptoms of MI, the incidence of primary VF decreases exponentially with time and becomes rare after 12 hours.[1,2] This marked time dependency hampers definition of

TABLE I Categories of Ventricular Fibrillation

Myocardial ischemia
VF ("primary")—high recurrence rate
Myocardial infarction
Primary VF—no shock or failure
Rx 95% success, recurrence rare, prognosis good
Secondary VF—shock or failure or both
Rx 30% success, recurrence common, prognosis bad
Iatrogenic VF—e.g., catheter, drugs
Recurrence rare (if cause recognized), prognosis good
Late VF—48 hours after acute event
Rx? success? recurrence common, prognosis bad

Rx = therapy; VF = ventricular fibrillation.

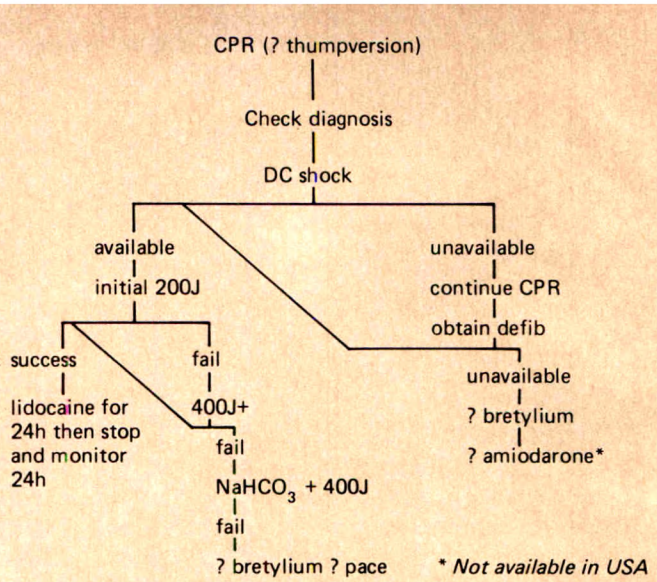

FIGURE 1. Suggested management for ventricular fibrillation. CPR = cardiopulmonary resuscitation; DC = direct-current.

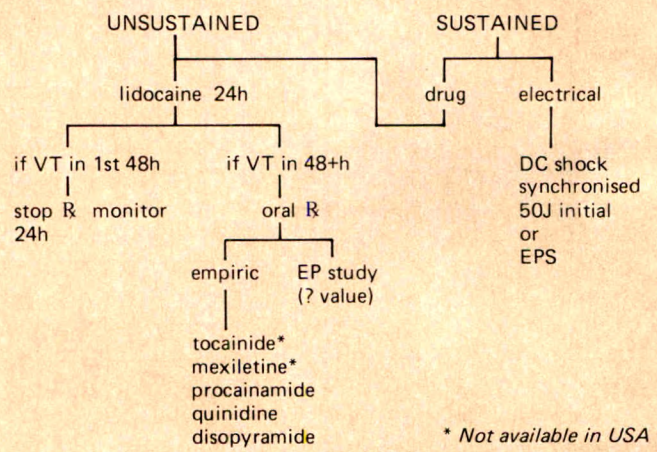

FIGURE 2. Suggested management for ventricular tachycardia (VT). DC = direct-current; EP and EPS = electrophysiologic study.

VF frequency, but current estimates suggest a rate of ≤30% in the first hour. The observed incidence of VF in the coronary care unit depends upon the patient population's time from onset of symptoms to admission. VF rates during transit to hospital are similarly time-dependent, but are also related to the duration of observation.

Early reports from coronary care units suggested that in approximately 10% of patients VF would develop.[3,4] However, in recent studies,[5,6] the VF rate in the coronary care unit has been closer to 5% in patients not given antiarrhythmic therapy. Whether this difference represents a true decrease in incidence or reflects a change in arrhythmia analysis is unclear. Various categories of VF are now recognized and include VF in the setting of myocardial ischemia, primary VF, secondary VF, iatrogenic VF and late VF. Resuscitation success rate and prognosis for each type is different (Table I). Some reports of coronary care unit experience do not separate these categories, whereas others detail only primary VF.

It has been widely believed that the incidence of all arrhythmias decreases exponentially from the onset of symptoms, but very little information has been derived from continously recorded electrocardiograms. VF is rarely missed in the coronary care unit, but recognition of other ventricular arrhythmias by observation or by alarm systems is not so reliable.

A recent study[2] investigated the natural history of ventricular arrhythmias in acute MI. Arrhythmia analysis was from continuously recorded electrocardiographic tapes. During the investigation, patients received no antiarrhythmic therapy other than for hemodynamically important arrhythmias. Patients enrolled in this investigation had not received beta-adrenoreceptor blocking drugs, diuretics, or digoxin either before inclusion or subsequent to their MI. In the first 4 hours after the onset of symptoms, all types of ventricular arrhythmias were relatively frequent but after 4 hours, primary VF and R-on-T ventricular ectopic complex frequency decreased rapidly and the incidence of other ventricular arrhythmias (ventricular tachycardia [VT], ventricular ectopic pairs and isolated ventricular ectopic complexes) appeared to increase. This bimodal distribution of arrhythmias comprises an early phase characterized by a high incidence of VF and R-on-T ventricular ectopic complexes that may reflect a reentrant mechanism. In the late phase, other ventricular arrhythmias predominate and possibly reflect a different pathophysiologic arrhythmia mechanism.

In patients with MI who have not received antiarrhythmic therapy, VT (≥3 consecutive ventricular ectopic complexes at a rate ≥120/min) is a relatively common arrhythmia, detected in ≤73% of patients within the first 24 hours of symptoms.[5,6] Longer runs of consecutive ventricular ectopic complex beats (≥10 consecutive complexes at a rate ≥120/min) occur in up to 27% of patients.[5,6] However, sustained VT is relatively uncommon at this time. Other ventricular arrhythmias (ventricular ectopic complex pairs and isolated ventricular ectopic complexes) are also common and are detected in almost 100% of patients during the first 24 hours of their illness.

TABLE II Relation of Warning Arrhythmias to Ventricular Fibrillation

	Frequency of WA	
	Total Group	VF patients
Lie et al[15]	59%	60%
El-Sherif et al[16]	55%	58%

Warning arrhythmias (ventricular ectopic complexes >5/minute, multiform, repetitive, R-on-T).
VF = ventricular fibrillation; WA = warning arrhythmias.

TABLE III Comparative Accuracy of Computer and Human Arrhythmia Detection. Ventricular Arrhythmia Detection—Conventional Versus Computer

		Accuracy (%)	
	Actual Incidence (%)	Conventional System	Computer
VF	5	100	100
R-on-T VECs	55	12	40
VT	28	11	88
VECs	90–100	66	95

VECs = ventricular ectopic complexes; VF = ventricular fibrillation; VT = ventricular tachycardia.
Figures are calculated for illustrative purposes.[1,2,3,17,18]

Importance of ventricular arrhythmias in acute myocardial infarction: Ventricular arrhythmias are important if they cause symptoms, are hemodynamically significant or have prognostic significance.

Unless rapidly treated, primary VF is fatal, although a small proportion of episodes do spontaneously terminate.[7] Management includes prompt application of a direct-current shock and should incorporate prophylactic therapy for 24 hours, because the electrophysiologic milieu that supported the initial event is unaltered by the direct-current shock and is likely to remain until the infarction process has undergone sequential change. Recurrence after 24 hours is unlikely. Figure 1 shows a suggested management plan for VF. Primary VF complicating acute MI appears to confer little or no late adverse prognostic significance.[8–10] One-, 5- and 10-year survival rates for resuscitated patients are excellent and are not different from those for patients whose infarction was not so complicated.

The lack of a generally agreed upon definition for VT confounds analysis of the importance of this arrhythmia. One study noted that VT occurring in the acute coronary care unit phase of infarction conferred no late adverse prognostic significance.[11] The immediate impact of VT depends upon its rate and duration. In acute MI, there appears to be no relation between VT and VF[2] and the decision to treat VT must depend upon clinical circumstances and physician preference. The treatment of rapid VT may be modified depending on whether the arrhythmia is sustained or paroxysmal. A suggested management strategy is shown in Figure 2.

Warning arrhythmias: A variety of ventricular arrhythmias have been suggested to be harbingers of primary VF[12] and are graded by the Lown classification.[13] Their predictive role was based on oscilloscopic observations of patients' electrocardiograms in the early phase of acute MI. Soon after establishment of coronary care units, much effort was put into detecting these so-called warning arrhythmias and suppressing them with lidocaine. Doubts regarding the value of this therapy were voiced[14] but it was not until the studies of Lie,[15] El-Sherif,[16] and their co-workers, using continuous electrocardiographic recording and analysis, that an accurate assessment of the relevance of warning arrhythmias was possible. Both studies showed that warning arrhythmias (defined as ventricular ectopic complexes with a frequency >5/minute, multiform ventricular ectopic complexs, VT, and R-on-T ventricular ectopic complexes) were as common in all infarct patients as they were in the subgroup who progressed to VF (Table II). This finding, which contradicted previous observations, can be explained by the inaccuracy of human observations of electrocardiographic displays (Table III).[17,18] However, human detection of an arrhythmia probably becomes more reliable with increasing or changing prevalence of the event. A change of frequency of R-on-T ventricular ectopic complexes has been reported before the onset of primary VF in selected infarct patients.[2] This change of frequency may be the phenomenon that aided recognition of R-on-T ventricular ectopic complexes by observers and became the basis for their categorization as the most "malignant" arrhythmia in the Lown classification. However, despite the association between a change of R-on-T prevalence and primary VF, the phenomenon appears insufficiently sensitive to operate as a practical predictor of VF.[2] No electrocardiographic event yet identified can predict satisfactorily the occurrence of VF. The role of monitoring in the coronary care unit must then be questioned because its rationale in detecting warning arrhythmias no longer has clinical purpose. However, substantial resources continue to be expended in equipping and staffing coronary care units to perform this task. This is not to deny the possible benefits of electrocardiographic monitoring, but if the relevance of arrhythmias were better understood, more appropriate monitoring systems might be developed. Current monitoring facilities that offer moderately reliable ventricular arrhythmia detection by real-time computers are valuable research tools but offer little in the clinical management of patients.

Prophylaxis of ventricular arrhythmias in acute myocardial infarction: The standard policy in some cardiac centers is to give no antiarrhythmic therapy except for the treatment of hemodynamically significant or symptomatic arrhythmias. VF, when it occurs, is promptly and aggressively treated. In other centers, unease regarding VF has stimulated the search for safe prophylactic remedies that could be administered to unselected populations of patients with suspected acute MI.

Many studies of prophylactic antiarrhythmic therapy in acute MI have been reported,[19] but few have provided definite conclusions regarding efficacy. Often, too few

TABLE IV Studies of Ventricular Arrhythmia Prophylaxis With Lidocaine

	N	Dose	VF Incidence (%) Untreated	Treated
Bennett et al[21]	256	Low	5.6	3.8
Mogensen et al[22]	77	Mod	2.7	0
Church and Biern[23]	86	Mod	6.8	9.5
Bleifield et al[25]	89	Mod	4.2	0
O'Brien et al[26]	300	Mod	3.4	4.5
Lie et al[20]	212	High	10.5	0

Mod = moderate; VF = ventricular fibrillation.
Adapted from De Silva et al.[27]

episodes of VF have occurred for a direct evaluation of drug effect. Inferred benefit from drug effect on VT, although often made, is no longer tenable[2] because this arrhythmia behaves differently and may have disparate pathophysiologic mechanisms. A statistically significant reduction of primary VF has been shown in only 1 controlled study. In this investigation, high-dose intravenous lidocaine was used.[20] The incidence of primary VF in the control group was 9%. No VF occurred in the lidocaine-treated group. These figures permitted identification of drug effect in a surprisingly small number of randomized patients. Other studies of lidocaine[21–25] have failed to show this benefit but none were of similar design[26] (Table IV). Uncontrolled but impressive data on prophylactic lidocaine have been reported by Wyman and Hammersmith.[27] Despite the paucity of evidence, it is likely that high-dose intravenous lidocaine prevents primary VF, but Lie et al[20] reported that the recommended regimen produced unwanted effects in 15% of patients. Most were minor. In an earlier, lower-dose study,[22] serious consequences of prophylactic lidocaine were observed in patients suspected of acute MI but in whom the diagnosis was not confirmed by sequential electrocardiographic and enzymatic analysis. In the study of Lie et al,[20] the consequences of drug administration to noninfarct patients was not reported.

Arrhythmogenesis is a topical issue. It has been suggested that subtherapeutic plasma levels of lidocaine in early acute MI might predispose to arrhythmia development. This important possibility has not been examined scientifically in clinical practice.

VF prophylaxis with other antiarrhythmic drugs has been investigated.[19,28] Many early studies were designed and conducted when the time-dependent nature of VF was unappreciated. Initially promising results with prophylactic disopyramide[29,30] have not been confirmed in later studies.[31,32] Prophylactic tocainide[6] and mexiletine[5] have proved highly effective in reducing VT, but assessment of the effect of these drugs on VF was precluded by low VF rates in the selected populations. The most important general conclusion to be drawn from these reports is that prophylactic oral antiarrhythmic therapy has little chance of preventing primary VF. Gastrointestinal absorption of most orally administered drugs is reduced by acute MI and by the administration of narcotic analgesic,[33] and it is unlikely that any could achieve "therapeutic" plasma concentrations within 1 hour of dosing. A delay of this magnitude is critical in the early phase of acute MI.

Successful prophylactic regimens require parental administration. The intravenous route is the fastest method of achieving satisfactory plasma levels, but may be the dosing method most likely to produce unwanted effects. Moreover, initiation of intravenous therapy requires skilled medical or paramedical attendance, precluding use of this route by the lay population or even by patients themselves.

Other approaches to ventricular arrhythmia control: Important factors responsible for arrhythmias in acute MI include ischemia, catecholamine release and electrolyte shifts. Dispersion of refractoriness is created and predisposes to the development of reentrant arrhythmias such as VF and R-on-T ventricular ectopic complexes. The pathway by which the basic disturbances produce the electrophysiologic changes is not well understood and metabolic interventions that have a good theoretical basis are not applicable to clinical management.[34]

Beta-adrenoreceptor blocking drugs that have an important role in the prophylaxis of sudden death after recovery from infarction may be useful in the acute stage. Most studies have been started too late to investigate this possibility, but in 1 study of metoprolol,[35] early benefit was claimed. Further investigation of the efficacy and safety of beta-adrenoreceptor blocking drugs in the first 24 hours of infarction is indicated.

Conclusions

Ventricular arrhythmias are a common complication of acute MI. The observed incidence of VF varies with time from the onset of symptoms, with a rate of >30% in the community and 4 to 10% in hospital coronary care unit populations. VF cannot be predicted, but the likelihood of the event is highest in the first few minutes after the onset of symptoms. VT is a common arrhythmia in acute MI and has a time course that differs from that of primary VF. Depending on its definition, it is present in <70% of patients but is only rarely symptomatic or of hemodynamic significance at this time and, if nonsustained, appears to have no late prognostic significance.

From these variables, a management strategy for ventricular arrhythmias in acute MI can be formulated. Therapy based on warning arrhythmias has no scientific foundation. The management of VF must be either expectant or prophylactic. Expectant management is safe, restricted only to those at risk and has an excellent immediate and long-term success rate. Well-trained staff and reliable and instantly available equipment are mandatory. Proved prophylactic therapy means using a high-dose lidocaine regimen. Although probably effective, the risk-benefit ratio of this strategy is still undefined.[36,37] The drug must be administered to patients who later are shown not to have sustained an infarct and who are not at risk of VF. They may constitute as much as 50% of coronary care unit admissions. Care

must be taken to avoid lidocaine overdosing, but in general the management demands less of the attending staff and may be particularly appropriate for patients who must be cared for in less-than-ideal cardiologic circumstances.

Except for VF, most acute phase ventricular arrhythmias probably do not require therapy, but those causing upsetting symptoms or those with hemodynamic importance should be treated. The required duration of therapy is difficult to define. An event in the first 24 hours may well be self-limiting and not recur after initial therapy. Events that do recur or that are considered to be likely to recur require oral therapy, the choice of drug being empiric or based on invasive electrophysiologic investigation.

No current strategy for ventricular arrhythmia prophylaxis or treatment in acute MI is satisfactory. More complete knowledge of arrhythmia mechanisms, improved drugs and well-controlled studies are necessary if this aspect of clinical management is to be scientifically based.
